77. Agglutination Titer in Infectious Diseases.—Klicenberger has encountered eight cases of typhoid in the last two years in which agglutination occurred once at 1 to 2,560; three times at 1 to 10,240; twice at 81,920 and once at 1 to 163,840. These high titers did not last over many days. In some cases of paratyphoid infection, the serum agglutinated at 1 to 81,920 and kept this up for over four months. In pyocyanus infection agglutination occurred at 1 to 40,960 in one case, but in two others only at 1 to 2,560. This same figure was obtained also in three proteus infection cases.

79. Treatment of Diarrhea by Reducing Sensitiveness of the Stomach.—Henius thinks that Fuld has hit the nail on the head by his statements in regard to "gastrogenous diarrhea," that is, diarrhea set up by a reflex action on the colon from the oversensitiveness of the stomach. Just as reflex vomiting can occur from this cause, reflex diarrhea may be started and maintained by it. Treatment should aim to soothe the irritable stomach. By deadening the sensibility of the stomach, the reflex action is arrested and the diarrhea is cured. Cocain may answer the purpose: ten drops of a 3 per cent. solution of cocain fifteen minutes before meals.

84. Treatment of Flat-Foot by Induced Shriveling of Ligaments.—Katzenstein induces hardening and shriveling of overstretched and relaxed ligaments responsible for flat-foot and other deformities. He discovered by accident the effectual action of the tanning process and then proceeded to apply it systematically. One of his cured patients is a youth of 15 who has been cured by this means of crippling and painful bilateral flat-foot disturbances. He does not even have to wear insoles now. Katzenstein uses formaldehyd for the purpose, injecting, for example, into the tibionavicular ligament from 0.5 to 1 c.c. of a weak solution of formaldehyd under local anesthesia. A plaster cast is then applied to hold the ligament in its shortened position. When the cast was removed after three or four weeks the ligament was firm and hard. He gives an illustration of an apparently almost normal child of 5 cured of extreme flat-foot and inward bowed legs. He injected the formaldehyd into the tibionavicular ligament and into the medial lateral ligament of each knee, with a plaster dressing for the three joints. He thinks that relaxed ligaments are the cause of deformity of bones far more often than is generally recognized. By detecting the loss of elasticity early it may be possible to ward off deformity and correct it by restoring the pull to the ligaments. This is a truly causal treatment of deformity and renders apparatus superfluous.

85. Neuropathic Equivalents in Infants.—Wilhelm relates the case of an infant of 8 months who died from pneumonia after an attack of diphtheria; for months previously it had had attacks of vomiting suggesting stenosis of the pylorus. As soon as the diphtheria developed, the vomiting stopped but began again after recovery, stopping anew as the pneumonia came on. Wilhelm suggests that the vomiting may have been a conditional reflex, and that this was arrested by the intercurrent disease. The vomiting occurred first in connection with some indigestion. The mother was extremely nervous and the inherited taint maintained the vomiting as a conditional reflex on the intake of food.

90. Development of New-Born Animals under Artificial Feeding.—Brüning found that young rats taken from the mother during the first few days of life and artificially fed

on food rich either in albumin and fat or in carbohydrates were lighter and smaller at the end of the nursing period than those left with the mothers. Artificial feeding with food rich in fat and albumin immediately after weaning caused a marked and progressive increase in weight. Food rich in carbohydrate after weaning, on the contrary, caused a decrease in weight so that the animals on the forty-second day were about the size of half-grown mice. When the latter group were placed on a mixed diet they increased in weight but did not come up to the standard of the group fed with an abundance of fats and proteins. Roentgen examination did not show any changes in the bones. The intestinal canal of the animals fed on carbohydrates showed the type of the herbivora, and that of those fed on proteins the type of the carnivora. The former have little fat tissue while the latter are quite plump. There was no marked difference in the intestinal flora of the two groups, but there was a relative scarcity of bacteria in the upper part of the intestinal tract in both groups.

92. Deep Cancers Cured by the Roentgen Rays.—Bumm and Warnekros state that after disappointing extensive trials of mesothorium and other radio-active substances, they returned to roentgenotherapy with a modified technic, and here report two years of most encouraging experiences. The secret of success, they say, is to use hard tubes, by the cross-fire technic, to generate 500 X units in the depths. As about six-sevenths of the rays applied to the surface fail to penetrate to a depth of 10 cm., fully 3,500 X units have to be applied to the skin to obtain the 500 units in the focus. They state that no serious injury results from this intensive exposure of the skin to the exclusively hard rays, even with 800 X units. At worst, the skin may blister but this heals in three or four weeks, and a month of a transient local dermatitis is not to be considered when balanced against the cure of malignant disease. Seven cases of advanced cancer of the uterine cervix, fourteen of the breast and one of the lung are reported, all showing remarkable benefit under the exposures, even the microscope confirming the complete retrogression of the cancer, as they show by slides of excised scraps. The tissues became indurated, with hyaline degeneration of the connective tissue, and there was not a trace of cancer by the fifth week in one typical case of a bleeding carcinoma in the uterine cervix, as large as a man's fist, the patient aged 37. The rays were applied externally alone, the distance from the focus 10 or 15 cm., the daily exposure totaling 60 or 80 minutes, the different fields of exposure overlapping so that each was exposed from 90 to 120 minutes. In two weeks the growth had subsided by one-half and by the end of the third week the retrogression continued spontaneously after the close of the course of treatment.

In one case the interval since treatment has been over a year and the cure has persisted to date. The patient, a woman of 42, was already in advanced cachexia with dyspnea from an inoperable recurrence of cancer of the breast. The lymph-nodes in the axilla were much enlarged, both above

and below the clavicle, and adherent. This patient returns every two or three weeks for a prophylactic exposure. One great advantage of Roentgen treatment over the knife is that any lymph-nodes involved or other metastases, feel the curative influence of the rays on their way to the deeper focus. Ovarian cancers proved the hardest to influence in their experience but fine results were obtained in 2 cases with metastases left after panhysterectomy for ovarian cancer.

94. **Intraspinal Injection of Salvarsan.**—This article reports extensive experiments on monkeys treated with neosalvarsan injected directly into the central nervous system in doses relatively much larger than are used in the clinic and three times as concentrated. One monkey by lumbar puncture was given—proportional to its weight—thirty times the amount given to patients, and yet it showed no signs of anything wrong, kept clinically healthy, and only the microscope revealed slight and circumscribed histologic changes. The dose was 3 c.c. of a 0.15 per cent. solution. With stronger solutions injected into the spinal canal or brain the nervous tissue showed signs of severe irritation, especially in the vessel walls and the glia. The monkeys injected subdurally and into the spine even with large amounts of the solution used on patients (0.15 to 300) were not affected deleteriously in the slightest and even the microscope failed to reveal the slightest change. The article is accompanied by fourteen pictures of the microscopic findings under the intensive dosage. The results of the research are very encouraging for the mild intraspinal use of neosalvarsan in Gennerich's dosage, that is, not over 6 c.c. of a 0.15 to 300 solution. (See also Berlin Letter in THE JOURNAL, June 20, p. 1979.)

96. **Passive Transmission of the Defensive Ferments.**—Fauser injected ten rabbits with serum from patients with dementia precox. The serum digested ovarian tissue or testicle tissue according as it came from a woman or man, and this discriminating property seemed to be transmitted to the rabbits' serum.

98. **Dyspepsia, Colitis and Cirrhosis of the Liver.**—Schütz gives the details of four cases in which primary dyspepsia brought on serious inflammation in the colon. A tendency to spontaneous healing was evident in two cases, showing that even quite severe bowel trouble is liable to retrogress spontaneously. This explains the occasional appearance of pus in the stools of patients with dyspepsia who yet never develop severe enteritis; a mild attack passes over undetected. The modification of the intestinal flora by the abnormal digestive processes may be the chief factor in the colitis.

111. **Mercury Test for Effusions.**—Zannini has been giving Morelli's test a thorough trial and found it extremely simple and reliable. He applied it in 13 cases of transudate and 35 of effusions, comparing the findings with those of the Rivalta test. In the 35 cases of effusions the Rivalta test was positive in all, but the Morelli test was negative in 15. Everything in these cases indicated a tuberculous process, confirming Morelli's assertion that effusions of tuberculous origin always respond negatively to the test. It is made by dropping three or four drops of the fluid into a glass filled with a saturated solution of mercuric chlorid. If the fluid is an effusion, a yellowish ring of mercury albuminate will form on the surface; it will either adhere to the walls of the vessel or it will sink to the bottom whole. This is the positive reaction. If the fluid is a transudate instead of an effusion, the mercury acting on the albumin forms numerous small flakes or granules which sink thus segregated to the bottom. This is the negative reaction.

112. **Spastic Ileus.**—Cauli discusses the present status of the conception of ileus from spasmodic contraction of some segment of the intestine and reports a case from his own practice. His patient was a robust boy of 17 with no pathologic antecedents. After ten days without bowel movement; he developed severe abdominal pain and vomited incessantly. There did not seem to be any specially tender points but sometimes the pain seemed more intense to the right, below the umbilicus, and sometimes more in the left iliac fossa. He could not retain even a sip of ice water, and during the paroxysms of pain the pulse was small and frequent, the face drawn. After four days of these symptoms there came a lull, the lad feeling very much better and getting up, but the bowels did not move and he continued to vomit. No effect was realized from morphin and enemas and the pains returned, becoming so intense that operative relief became imperative. Nothing pathologic was found at the laparotomy except that the small intestine over a stretch 20 cm. long was contracted and also the descending colon and flexure, the segment not larger in diameter than one's little finger. Otherwise the viscera seemed normal; the intestines above the contracted segments were not much dilated. The abdomen was sutured without further intervention and the vomiting ceased and bowel functioning was restored after a few days.

Two days after his discharge from the hospital he returned with his old symptoms but in a milder form; he was kept under observation for a few weeks during which periods of complete well being alternated with periods of vomiting but the intestines moved freely. Treatment included opiates, atropin, hot applications and suggestion. No effect from the atropin could be detected. By the end of the sixth week after the first appearance of symptoms he was apparently entirely cured and has had no signs of trouble since. The good general condition during the intervals between the attacks of pain was noticeable; even when the vomiting and the occlusion of the bowels kept up, yet the lad felt well and his pulse was good during the intervals. This is the opposite to what is observed with true ileus.

A FEW POINTS OF PRACTICAL IMPORTANCE IN OBSTETRICS, GYNECOLOGY AND ABDOMINAL SURGERY*

E. GUSTAV ZINKE, M. D.
CINCINNATI

The prodigious advancement made in medicine and surgery during the past forty years has made it impossible for one mind to master every department pertaining to the study and practice of our profession. To be as nearly perfect in one department, and to know as much of each of the other branches as time, talent and circumstances will permit, is all the ablest of us can do.

In this Section our attention is limited to obstetrics, gynecology and abdominal surgery. It takes a capable man to be master of one of these branches, but a far more able man to be master of all three. It is the object of your chairman to dwell briefly on a few important points in each, namely, intestinal stasis, painless operations, Roentgen-ray therapy in gynecology and abdominal surgery, the curative effect of radium, the Percy treatment of inoperable carcinoma uteri, the compromise operations of obstetrics, the treatment of placenta praevia, and surgery in the treatment of puerperal eclampsia.

INTESTINAL STASIS

This is unquestionably one of the most important subjects before the medical profession to-day and it is, to a large extent, for the abdominal surgeon to solve most of the details of this comparatively new phase of an old problem, and to corroborate, as far as possible, the epoch-making work and teachings of Sir Arbuthnot Lane. In his address, delivered at the North-East London Post-Graduate College, Nov. 1, 1913, Lane¹ says:

By chronic intestinal stasis I mean that the passage of the contents of the intestinal canal is delayed sufficiently long to result in the production, in the small intestine especially, of an excess of toxic material, and in the absorption into the circulation of a greater quantity of poisonous products than the organs which convert and excrete them are able to deal with.

In consequence there exist in the circulation materials which produce degenerative changes in every single tissue of the body or which lower its resisting power against invasion by deleterious organisms.

Perhaps the best scientific confirmatory evidence I can put forward of the harmful effect of defective drainage, both of

the body as a whole and of the several tissues which contribute to it, has been afforded recently by the remarkable experiments of Carrel in the growth of living tissue, in which he has shown that tissues are immortal, and grow to the greatest advantage if the drainage of their toxic products is carried out effectually.

Owing to unsuitable diet in infancy and to the habitual assumption of the erect position, delay of fecal material takes place in the large bowel, or cesspool, of the gastro-intestinal tract, or, as it can be best described, the "general drainage system of the body." In consequence of this, new membranes or resistances to downward displacement are formed by the crystallization of lines of force upon the surface of the peritoneum along which strain is especially exerted.

Thus he explains the formation of the "bands," "kinks," "folds," "veils" and "membranes" to which his own name and that of Jackson, Treves, Reid and of Jonnesco and Juvara, have been attached. It is the formation of these new structures which explains the occurrence of stricture of the bowels, of appendicitis, of disease of the ovaries, of cancer of the cecum and of the rectum. It further serves to solve the mystery of elongation and dilatation of the duodenum, the spasmodic contraction of the pylorus, the consequent dilatation of the stomach from accumulation of its contents, and the "cardiospasm" of Plummer.

More than this, the changes mentioned above may terminate in ulceration and perforation about the pylorus and lesser curvature of the stomach and even cancer of this organ may result. Or changes may produce infection of the liver and gall-bladder, or lead to the formation of gall-stones, cholecystitis or malignant degeneration.

Other symptoms enumerated by Lane are: the loss of fat; wasting of muscles; degenerative changes in the skin with alteration of its texture and color; the temperature, in uncomplicated cases, is subnormal; stasis always exists in Raynaud's disease; there is mental apathy, stupidity or misery and, occasionally, melancholia or even imbecility and suicidal tendency. Neuralgia and neuritis are frequent; epileptiform tic and headaches are often present; want of control of temper which may lead to misery or even crime. Patients complain of rheumatoid aches and pains in muscles and joints; the thyroid gland wastes; the blood-pressure may be raised or depressed; the breasts show degenerative changes and cancer readily develops in them. Organs prolapse and change in size, shape and weight. The patient becomes short of breath on exertion, resembling asthma; but this may be due to distention of stomach or intestines interfering with the action of the heart. Most of the degenerative changes affecting the heart appear to be due to auto-intoxication. The kidneys may become affected. The hair of the head loses color early and

* Chairman's address, read before the Section on Obstetrics and Gynecology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, June, 1914.

1. Lane, Sir W. Arbuthnot: On Chronic Intestinal Stasis, Brit. Med. Jour., Nov. 1, 1913.

falls out; hair grows in places in which it is ordinarily inconspicuous or absent. The pancreas becomes infected from stasis of the duodenum, resulting in chronic induration, inflammation and finally cancer of this organ. Pancreatic diabetes may ensue. Degenerative diseases of the eye are produced and vary with the degree of auto-intoxication.

According to Lane, the direct changes resulting from the lowered resisting power of the tissues, produced by auto-intoxication, are: infection of the gum, causing pyorrhea alveolaris; tuberculous infection, not produced by direct inoculation; rheumatoid arthritis, which cannot develop except in the presence of defective drainage of the gastro-intestinal tract; infection, directly or indirectly, of the genito-urinary tract, through the blood-stream (by organisms other than tubercle) producing nephritis, cystitis, pyelitis, endometritis, salpingitis, etc.; development of adenomatous tumors in the thyroid gland, or general enlargement of this organ, or of exophthalmic goiter; Still's disease; infections of the skin of a pustular nature; infections of the large intestine by organisms which produce the several varieties of mucous and ulcerative colitis; and ulcerative endocarditis.

Lane states that he has "chosen merely a few obvious, typical, indirect results of the auto-intoxication of chronic intestinal stasis" and that "the point of practical interest . . . is that the drainage scheme be made to work efficiently . . . by mechanical means or by operative interference, and that the resisting power of the tissues of the body is such that they can destroy the organisms or poisons, if not advanced too far or if cancer has not developed;" and, "nothing is more remarkable in the whole range of surgery than the result of the removal of the large bowel in a case of rheumatoid arthritis. The transition is abrupt and startling."

The treatment varies: The non-operative treatment consists in the use of paraffin oil before each meal, the application of a spring support to the abdomen below the umbilicus to keep up the "transverse colon, cecum and other prolapsed viscera," and "to put into the stomach as little food as is likely to decompose and become poisonous in its passage through the intestines."

Operative treatment is resorted to only when the above or other modes of treatment fail and may necessitate the removal of the appendix when it interferes with the lumen of the ileum; or to "short-circuit" the bowel, by dividing the ileum and putting it into the pelvic colon. If the colon is freely movable and pendulous, Lane always removes it down to its junction with the sigmoid; his rule is: *Remove the large bowel, if it may be easily effected, if not, be satisfied with ileocolostomy. Gastro-enterostomy for duodenal distention, even if there is ulceration, is, in Lane's opinion, both unnecessary and harmful. If the ulceration has caused considerable reduction of the lumen of the pylorus, he resorts to gastro-enterostomy. Lane also performs gastro-enterostomy in ulceration of the stomach (in the absence of cancer) in addition to short-circuiting, with or without colectomy. He thus removes the strain from the lesser curve, effectually draining the stomach.*

Those who have carefully studied Lane's work on intestinal stasis, and the case reports of him and his followers, can only help but be profoundly impressed

by the reports of the results obtained from the operations of gastro-enterostomy, ileocolostomy or colectomy, or of all three, whether in the same subject at the same time or at different times. The profession is by no means unanimous in its opinion as to the real necessity of these heroic operative procedures for the relief of chronic intestinal stasis. Deeper delving and further investigations on the part of the internist and the abdominal surgeon alone will solve the problem.

PAINLESS OPERATIONS

Crile's kinetic theory of shock and its prevention through anoci-association² has found favor with many surgeons. There are, however, not a few who are averse to Crile's new method. The objections most writers offer are, that the time lost in making the injections of novocain and quinin-urea-hydrochlorid is considerable, that the abdominal walls remain more or less rigid, and that the numerous and extensive injections of both drugs, necessary to anesthetize the field of operation, have a tendency to devitalize the structures involved and thus cause delay in union of the parts as well as create a predisposition to the formation of stitch-hole abscesses. Many admit, however, that "anoci-association" is an ideal and practical method. The most serious operations may be performed without the slightest pain and with total absence of shock, while the clinical results, which Crile and his associates have obtained, leave naught to be desired. In 1908 their mortality was a fraction over 4 per cent.; in the last 1,000 operations (not selected cases) the mortality was reduced to 0.8 per cent. These figures speak for themselves and are deserving of serious consideration.

ROENTGEN-RAY THERAPY IN GYNECOLOGY AND ABDOMINAL SURGERY

Many of our surgeons look on roentgenotherapy as the sovereign remedy in uncomplicated cases of uterine hemorrhages. Since, however, in the opinion of some writers, the cure is obtained solely through the destruction of the ovarian follicles, they caution against the use of the Roentgen rays in young and nervous women. Others maintain that in young women the amenorrhea which follows the application of the Roentgen rays, is only transitory; that a permanent sterilization is almost impossible; that in women near the menopause active follicles are rarely present, and destruction of the ovaries is only a precursor to the climacteric period. The appellation, "Roentgen castration," is therefore, a misnomer and incomparable to surgical castration.

The experience of Bumm, Krönig,³ Gaus, Döderlein, Kelly, Burnam, and others with the effects of Roentgen rays on fibroid tumors of the uterus show that uterine hemorrhage may be successfully arrested; that, frequently, the tumors diminish in size; occasionally, even a cure may be effected, though not infrequently, the tumors remain as large as before. All agree that a timely myomectomy or hysterectomy yields the most satisfactory result. The administration of the Roentgen rays is limited to those cases in which extirpation of the tumor, or of the uterus, is inadvisable and relief from hemorrhage or other symptoms alone is sought.

2. Crile, George W.: The Kinetic Theory of Shock and Its Prevention through Anoci-Association (Shockless Operation), Cleveland Med. Jour., 1913, xii, 513.

3. Krönig, B.: Die Strahlentherapie in d. Gynäkologie, Strahlentherap., 1913, v, No. 2.

THE CURATIVE EFFECT OF RADIUM

The curative effect of radium on malignant disease has been vigorously assailed. Judging from the good results obtained from radium, mesothorium and the Roentgen rays, in the hands of such men as Krönig, Gaus, Döderlein, Dominici, Kelly, Burnam, Park, Parker Syms,⁴ and the Ransohoffs, as well as my observations in my own cases and those of others, the scathing adverse criticism of recent date seems uncalled-for and wholly unjustifiable. Some of the favorable results obtained, especially those from radium and mesothorium, are definite and unmistakable; and while it is, perhaps, too soon to speak of the good achieved with these remedies in terms positive and absolute, it is neither fair nor just to condemn them unqualifiedly.

For the present we know that in all operative cases the knife is the best agent for combating malignant disease; and that radium, mesothorium, as well as the Roentgen ray, have proved of unexpected value in some of the inoperable cases, as well as in some of the superficial forms of cancer. Therefore, it behooves us to encourage the work of those who have occupied themselves with determining the value of these remedies in the treatment of malignant disease.

THE PERCY TREATMENT OF INOPERABLE CARCINOMA UTERI

I feel it obligatory to speak a word in favor of this treatment of inoperable carcinoma uteri. Since witnessing the work of Percy in Chicago last fall, I have had an opportunity of seeing two cases of inoperable cancer of the uterus.

In one, Mrs. X, aged 48, coming into my care Nov. 15, 1913, the actual cautery (Percy method without opening the abdominal cavity) was used five different times at intervals of one week, two weeks and four weeks. At the end of that time only a small portion of the body of the uterus remained, and the vagina with the region formerly occupied by the cervix and lower uterine segment, appeared perfectly healthy, but an offensive watery vaginal discharge continued. The patient then received, at intervals of one week, three applications of radium (80 mg.) by Dr. Louis Ransohoff. The result was most marked and highly satisfactory. What there was left of indurated tissue in the vaginal vault, tenderness of the parts and of offensive discharge, disappeared promptly; the patient gained rapidly in weight, and is to-day, so far as the eye can see and the finger can feel, in every respect a healthy woman. Within the last seven weeks she has gained 20 pounds.

The other, Mrs. Y., aged 35, was first seen about the middle of March. This, too, was an inoperable case of carcinoma uteri. Up to this time the Percy method (not opening the abdomen) has been employed three times with, apparently, the same satisfactory results as in the first case. She is now ready for the radium treatment.

THE COMPROMISE OPERATIONS OF OBSTETRICS: THE INDUCTION OF PREMATURE LABOR, THE USE OF THE HIGH FORCEPS, VERSION AND EMBRYOTOMY ON THE LIVING CHILD

In considering the so-called compromise operations, my sole object is to awaken an interest in the new therapy of narrow and contracted pelvis which, after

the doctrine of narrow pelvis had been formulated by Litzmann and Michaelis of Kiel, has been so beautifully worked out by German obstetricians. Briefly stated, this new treatment consists of the test of labor, hebosteotomy, symphyseotomy, or abdominal cesarean section.

The hope has been expressed that the induction of premature labor, the application of the high forceps to a floating head above the pelvic brim, version, or embryotomy on a living child, might be, eventually, eliminated from obstetric practice. This hope has been realized only to a limited extent.

The induction of premature labor is to-day as popular in England as ever and is more favored in some parts of Germany. The high forceps continues, more or less, in favor in France and in this country, and version still enjoys well-deserved popularity. Aseptic midwifery and a more intelligent care of the premature infant have considerably reduced the maternal as well as fetal mortality of artificial labor. Asepsis in the use of high forceps or version has also been of value, though the maternal and fetal mortality has not, thereby, been markedly reduced.

The application of forceps to a freely floating head above the pelvic inlet, or to a head which will not engage, but steadily remains above the brim, is, with the knowledge of to-day, no longer considered good practice. A judicious perseverance in the use of high forceps in cases in which the os is fully dilated, the membranes ruptured and the head fixed at the inlet, is justifiable; but great care must be exercised to avoid injury to the child's head and damage to the soft parts of the mother. Prolonged and violent traction on the head, and the repeated introduction of the forceps by the same attendant or by different operators, cannot be too severely condemned.

Embryotomy on a living child can be regarded as justifiable only in cases of excessive hydrocephalus, extensive spina bifida, double monsters or when the fetal head is impacted in the pelvis and the child's life already seriously endangered, or when there is risk of rupture of the uterus, as in a case of impacted shoulder with excessive attenuation of the lower uterine segment and marked retraction of the contracted fundus. In most of these cases, version is impossible without rupture of the uterus.

Version is justifiable only in those instances in which the head is fixed on the brim of the pelvis, the mother's soft parts are uninjured, the uterus not over-distended, and a reasonable trial of the forceps have failed to deliver. (Early external, or combined version on the head or feet, as in transverse or oblique presentations, is not included here.)

The new therapy of narrow pelvis means: Send your patient to a hospital before labor begins, and give her the benefit of the test-of-labor; if this fails, perform hebosteotomy or, if need be, cesarean section. Under this management 80 per cent. of more than 30,000 patients with narrow pelvis have delivered themselves spontaneously; 15 per cent. of the patients have required hebosteotomy, and in only 5 per cent. was a cesarean section necessary. In all the maternal mortality was 0.1 per cent., and the fetal mortality about 4 per cent.

THE TREATMENT OF PLACENTA PRAEVIA

This is still an open question. Those who advocate abdominal cesarean section in every case of placenta praevia are as mistaken as those who will not admit

4. Syms, Parker: The Prevention and Cure of Cancer, New York State Med. Jour., May, 1913.

that hysterotomy is ever necessary in this condition. The great majority of cases of placenta praevia, it is true, may be favorably treated by the use of the tampon, the rubber dilator, version or slow extraction of the child, so far as the mother is concerned. Not so with the child; the majority, or at least a very large percentage, of the children perish under this treatment. In my opinion abdominal hysterotomy is indicated in every case of placenta praevia in which the hemorrhage cannot be controlled, no matter what the condition of the cervix, the character of the child's presentation or the location of placental implantation. Thus, if the placenta has developed normally, the hemorrhage from a placenta praevia centralis may be readily controlled if the os is dilatable, and the presentation vertex or breech; but hemorrhage may be difficult or impossible of control in a case of placenta praevia lateralis, marginalis or partialis, if the placenta is abnormally developed (for instance when the chorionic villi have penetrated the muscularis) and when, in connection with this condition, the cervix is elongated or the os very rigid, and the presentation of the child such that a correctly placed tampon or the insertion of a rubber balloon will neither control the loss of blood, nor cause obliteration of the cervix or dilatation of the os. Of those obstetricians who put so much stress on the importance of the life of the child when advocating cesarean section for eclampsia, yet strenuously argue against cesarean section in the treatment of certain forms of placenta praevia, permit me to ask: Is not the life of the child to be considered as much, and even more, in cases of placenta praevia than in eclampsia? The child delivered through the abdomen in a case of placenta praevia has a far better chance for life than one born in the same manner in eclampsia.

THE MERITS OF SURGERY IN THE MANAGEMENT OF PUERPERAL ECLAMPSIA

In a recently published paper on eclampsia, read in New York,⁵ we read the following: "The practitioner who seeks to learn from medical literature how the toxemias of pregnancy are best treated, may well feel that he has authority for the most radical treatment on the one hand and for shameful neglect of the patient's interest on the other."

In April, 1913, two papers on the treatment of eclampsia were read before the New York State Medical Society. One advocated vaginal cesarean section as one of the methods of emptying the uterus in the treatment of this disease, and the other maintained that the medical care of puerperal convulsions has given the best results, so far as the mother is concerned.

The writer of the more recently published article refers to these two papers as follows:

Any one reading those two papers on eclampsia would be in serious doubt as to how to treat a case of toxemia, because he is told on the one hand that the only real hope for the eclamptic patient lies in the immediate emptying of the uterus, although a number will die in spite of this treatment, and on the other hand he is assured that the only safe method of treatment of eclampsia is by purely medical means, though a certain number of patients, approximately the same, will be lost by following this method.⁶

The author of the paper of recent date, just referred to, does not quote a single sentence from either paper

to which he alludes. This we may readily pardon; but when, carelessly or wilfully, misrepresentation is added to seemingly specious argument, it must be corrected. Personally, I welcome and always respectfully consider the severest criticism, and, as this subject is of the greatest importance to child-bearing women, I regard it as my solemn duty to make the correction on this most auspicious occasion.

The author in question states that "*approximately the same number of patients die*" when treated by "*purely medical means*" as when subjected to "*the immediate emptying of the uterus.*" In my paper, to which this writer unquestionably refers, conclusive proof is furnished that, under strictly medical treatment, the collective maternal mortality is really less than 13 per cent., and that the most favorable statistics of the maternal mortality of eclampsia, when surgical means have been employed, do not fall below 28 per cent. No effort is made to prove my statements incorrect; and yet this writer has the temerity to state in the same paper that "*the published results of a large number of cases*" (of eclampsia) "*in which the abdominal cesarean section has been performed, show that the maternal mortality runs somewhere between 40 and 50 per cent.*"⁶

My own paper⁷ on eclampsia, read at Rochester before the New York State Medical Society, in 1913, is an earnest protest against the immediate emptying of the uterus after the first convulsion, or the indiscriminate performance of cesarean section, to the exclusion of every other means, for the relief of puerperal toxemia. The arguments brought forth in my paper have not been refuted, and I reiterate: *Up to the present time, we have no better means of combating puerperal eclampsia than by the hypodermatic use of large doses of veratrum viride, free saline catharsis, hot baths or packs, strict milk diet and, if the patient be in labor, to facilitate its progress with or without the aid of the forceps or version on the feet.* Seeing is believing. Try this treatment and you will be convinced! Let us seek triumph only in truth!

Peterson's⁸ last paper on abdominal cesarean section for eclampsia, appeared in the last issue of the *American Journal of Obstetrics*. Like all of his literary efforts, this paper again reveals his enormous capacity for work, and that he has plenty of time in which to do it. In this paper he furnishes the statistical evidence that the maternal mortality of puerperal eclampsia may be reduced to a little less than 13 per cent. when abdominal cesarean section is performed early; in other words, the maternal mortality of this disease can be made as low with abdominal hysterotomy as when treated by purely medical means.

For the sake of argument, and for the sake of argument only, this statement is accepted. It alone is sufficient to demonstrate that Peterson has, virtually, solved the problem in favor of the medical treatment of eclampsia. Who will now advocate abdominal cesarean section in every case of puerperal convulsions, if the same—and even better results—can be obtained with medical care?

NEWER POINTS OF VIEW REGARDING THE
PART PLAYED BY DIFFERENT
FOOD SUBSTANCES IN
NUTRITION*

LAFAYETTE B. MENDEL

Professor of Physiological Chemistry at the Sheffield Scientific School
of Yale University

NEW HAVEN, CONN.

For the continued performance of their physiologic functions and for the maintenance of their material integrity, living organisms are dependent on an adequate supply of suitable nutrients. Their needs in this respect are evidently not uniform at all times. Periods of growth and development, of convalescence and repair, determine special requirements that are not encountered at other epochs in the life-cycle, just as rest and activity alternate in making unlike demands on the organism during the routine of each day. It was realized, long ago, that these varied manifestations of the bodily mechanism may create specific demands in respect to the food substances; but it was a forlorn hope to expect to penetrate far into the mysteries of nutrition until some definite and fairly comprehensive knowledge regarding the chemical make-up of the products taken into the body as food had been unveiled. An elementary understanding of the fate of the fats and carbohydrates came earliest, because these foodstuffs were the first to have their chemical constitution unraveled. The story of the metabolism of the protein substances is only now beginning to keep pace with the newer knowledge of the structure of these highly complex nitrogenous compounds, and there are chapters bearing on numerous other factors in the food intake—on the place of the inorganic salts, the lipoids and diverse accessory features in the dietary—that still remain to be written even in their broadest outlines.

To speak of "newer" points of view regarding the rôle of the different food substances in nutrition, as I am expected to do, implies a contrast of to-day with yesterday in this progressive domain of physiology. One need not turn back far to reach the days of Liebig, to whom, above all others, are due the beginnings of present-day knowledge of the constitution of foods, tissues and excreta. In Moleschott's popular "Physiologie der Nahrungsmittel," published in 1859, the chief concern of nutrition was portrayed as the production of good blood. He wrote:

One of the foremost questions which humanity will always address to the physician, is how good, healthy blood, capable of development, can be attained. And, modify the inquiry as they will, all those who are concerned therewith are forced by experience to admit, whether it be frankly or with reserve, that our thoughts and our loves, our children and our powers depend on our blood—and our blood on food.

Accordingly, Moleschott further maintained that vigorous nutrition is the consequence of efficient formation of blood; so far as the latter process means an enrichment of the circulating fluid in protein substances, the vigorous nutrition would express itself, above all, in the muscular tissues. "The more meats, legumes and cereals are consumed and digested," says Moleschott, "the plumper are the muscles, the firmer

their fibers, the more powerful their action." Other diets, of rice, or vegetables, or fish, were pictured as leading to an enfeebled musculature. For the fats and carbohydrates there were known depots other than the muscles. Not until the work of Carl Voit was the principle of nitrogenous equilibrium definitely established for the animal body.

The vague and indefinite generalizations of a generation ago in respect to the functions of the food-stuffs have slowly been transformed into the more tangible theories and suggestive hypotheses of the passing decade. To give you some more concrete ideas of what these changes have involved I may refer to the teaching current in my own student days, more particularly as it is related to nitrogenous metabolism. Sir Michael Foster wrote in 1891: "At all events the greater part of the proteid material of the food enters the blood as proteid material, either as peptone or in some other form, and is carried as proteid material to the tissues." The latest dictum respecting this phase of absorption presents an entirely different point of view. Proteins are now understood to be disintegrated in the digestive tract into relatively simple nitrogenous fragments, the amino-acids, not exceeding twenty in number. It is these digestion products, absorbed into the blood-stream and now demonstrated beyond peradventure to be present there, that represent the real form in which the protein intake of the body is transported throughout the organism. Protein metabolism has at length become essentially a question of the behavior of amino-acids in the body—their uses and fate.

So far as the nitrogenous transformations are concerned, the amino-acids are the center of interest in nutrition, the pivot about which the modern conceptions turn. For him who would understand the real significance of the proteins in the functions of the organism there is no escape from the necessity of appreciating clearly the nature of the amino-acids—those derivatives which arise when, either in the laboratory of the chemist or in the alimentary processes of digestion, albuminous substances are disintegrated. A generation ago it was the superficial distinctions between animal and vegetable proteins, between albumins and globulins and albuminoids that formed the basis for discussions of relative nutritive merit. To-day we are more concerned with the question whether this or that protein, whatever its biologic origin, will yield the characteristic, desired amino-acids, such as tyrosin and tryptophan, leucin and lysin, glycocoll and cystin, histidin and arginin. Our attention is fixed on the building-stones or units out of which the great protein structures are put together.

Instead of referring to the proteins in terms of their physical properties or empirical composition—their content of carbon, hydrogen, oxygen, nitrogen or sulphur—at least so far as the problems of nutrition are involved, the time has arrived for estimating their behavior in the organism on the basis of the quota of each of about eighteen well-defined amino-acids which the individual representatives of this group of food-stuffs can yield. Most, if not all, of these amino-acids are essential for the construction of tissue and the regeneration of cellular losses. In proportion as any specific protein can furnish these constructive units it may satisfy the nutritive needs of the body. The efficiency of the individual protein in this respect must depend on the minimum of any indispensable amino-

* Read at the joint meeting of the Section on Practice of Medicine and the Section on Pathology and Physiology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

acid that it will yield; for it is now known that some of them cannot be synthesized anew by the animal organism. If, for example, a protein or mixture of proteins comparatively deficient in their yield of the sulphur-containing amino-acid cystin be furnished alone to supply the body's nitrogenous requirement, the production of new, cystin-yielding molecules of protein will be limited by the amount which is available in the diet. An excess need not be wasted, for it can be burned up like sugar or fat to provide energy; but new construction or growth is limited by the minimum of the essential unit.

Although a supply of all or most of the characteristic amino-acids derived from typical proteins is essential for the construction of new tissue or the repair of the old, it by no means follows that all of them are inevitably needed in the ordinary function of maintenance, that aspect of nutrition characterized by the preservation of unchanged body-weight in the adult from day to day. Nevertheless, certain amino-acids are absolutely indispensable even in maintenance. This is well shown in recent observations conducted by Osborne and myself under the auspices of the Carnegie Institution of Washington. We have succeeded in keeping small animals (albino rats) during long periods on mixtures of isolated protein, fats, carbohydrates and inorganic salts as they are present in the protein-free fractions of milk. The advantage of this experimental procedure lies in the fact that it is possible to test, as we have done, the nutrient efficacy of individual proteins. The upshot of our now extensive experience has been to demonstrate pronounced differences in proteins from different sources. Some, like the proteins of milk, the edestin of hemp-seed, the albumin of egg-white, are individually capable of satisfying the nitrogenous needs of the body at all stages of its development. Chemical analysis has disclosed the potential existence of most of the familiar amino-acid groups in each of these protein complexes. When the gliadin of wheat, a prominent protein of this seed, is fed as the sole protein, adult animals are suitably maintained; but growing animals cease to increase in body-weight, remaining in nutritive equilibrium without growth, unless the amino-acid lysin $\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}(\text{NH}_2)\text{COOH}$ is added to the gliadin-food.

Thereupon growth is promptly resumed. The explanation becomes apparent in the fact that gliadin is almost entirely devoid of the lysin radical; and inasmuch as this is obviously needed for new protein construction, growth cannot proceed until the missing unit is supplied. Again, zein, the most conspicuous protein of the maize kernel, fails to yield either lysin or

and accordingly is entirely inadequate to meet the nitrogenous needs of animals in respect to either maintenance or growth. It may be fed in the greatest abundance; yet the animals decline in health unless the zein is supplemented by some more perfect protein. If the amino-acid tryptophan is added to the imperfect maize protein, maintenance of body-weight, without growth, is promptly established. Evidently tryptophan is indispensable for some physiologic function quite apart from increase in tissue substance. If both tryptophan and lysin are added to the zein, the diet thereupon becomes suitable for growth. In

glycocoll, likewise missing in zein as in several other proteins, we have an instance of an amino-acid which can undoubtedly be manufactured when it is needed. From these facts it is apparent how essential certain amino-acids are in the nutritive processes and how unable the body is to synthesize some of these anew.

I trust that this hasty review has given emphasis to the contention that the problem of protein metabolism has largely become one of amino-acid supply. Provided only that they are rendered free and available by the digestive processes, the body cares little whence its amino-acids are obtained. Meat proteins, egg proteins, cereal proteins—all serve in the same sense. Indeed, the amino-acids themselves, isolated in the chemical laboratory, appear to be equally available. We begin to understand why a diet largely made up of corn with its abundance of the imperfect zein and its relative poverty in more complete proteins may be poorly suited for growing individuals; why corn is so advantageously supplemented by a little skimmed milk with its casein and lactalbumin; why gelatin, which does not yield tyrosin, tryptophan or cystin, fails by itself to meet the demands of the body for nitrogenous pabulum; why a low intake of a suitable protein may be infinitely more advantageous to nutrition than a surfeit of an "incomplete" protein.

Nor is the story of the rise of the physiology of the amino-acids ended here. These compounds furnish a superior medium for the growth of bacteria, not infrequently yielding products of pronounced toxicity or pharmacologic potency. A series of amines ranging from simple forms to complex types owe their origin to the action of micro-organisms on proteins, both outside of the body and within the alimentary tract. Putrescin, cadaverin, tyramin, histamin are derived from the amino-acids arginin, lysin, tyrosin and histidin, respectively. Likewise the widely vaunted alimentary offenders, indol and skatol, are chargeable to the putrefaction of the tryptophan group in the protein molecule; phenol and cresol are similarly derived from tyrosin. Thus many of that vague and heterogeneous collection of compounds once convincingly included in the indefinite expression "ptomaines" are doubtless nothing else than the fragments of amino-acids that have fallen sacrifice to bacteria before they could be absorbed intact into the bloodstream. Now that the production of these more or less toxic amines and alcohols is clearly referable to the action of known types of bacteria on individual amino-acids, the way to avert the malaise or more serious consequences with which the putrefaction products are so often charged may be a step nearer. Gelatin, for example, furnishes no tryptophan, tyrosin or cystin; the intestinal bacteria are therefore unable to liberate indol, phenol, hydrogen sulphid or mercaptans from it.

To still another domain the discovery of the amino-acid structure of the proteins has admitted fresh rays of light. The phenomena of immunity, creating almost an entire new science of immunology; the precipitin reactions; anaphylaxis and its varied manifestations—all of these point to the participation of proteins; and, what is more significant, owing to the highly specific character of the responses, they postulate the existence of individual proteins in numbers far exceeding the possibilities suggested by the ordinary criteria of individuality. How are we to conceive of a hundred

or a thousand specific albumins from as many tissues and individuals? We need merely grasp the convenient hypothesis furnished by our knowledge of the amino-acids which they yield. Assuming that ten different amino-acid derivatives are united even without duplication to form a single protein, mathematical calculation indicates the possibility of over three million different combinations; for eighteen amino-acids the possible combinations have been estimated to exceed millions of millions. In the face of such figures one realizes what specificity may really mean when thousands of structurally isomeric compounds can theoretically, at least, yield precisely the same proportions of the same amino-acids and yet remain distinct in respect to the relative arrangement of their constituent units. The development of an almost innumerable number of special enzymes, as suggested by Abderhalden's recent studies now widely applied in serodiagnosis, likewise finds the possibility of an explanation in what has just been noted. A thousand structures may require a thousand different keys to unlock them.

It might be illuminating to dwell further on other consequences entailed by the development of the biochemistry of the amino-acids; but we must return again to the physiology of two decades ago for a reminder of other changes that have been wrought by the hands of progress. Urea was, of course, recognized as the predominant excretory end-product of nitrogenous metabolism. Its history was difficult to follow, and almost entirely obscured. Foster voiced a then current belief in his widely studied text-book in suggesting that a large portion of the urea leaving the body by the urine is formed from the creatin of the muscle, though the objections to such a theory were already obvious to him. The normal presence of creatinin in the urine offered a difficulty which was not entirely solved by charging its origin to creatin ingested as meat. Nor was only creatinin left as a source of confusion. Uric acid and other excreted products remained to be accounted for, as they occurred in varying amounts in the urine.

Foster wrote:

Urea is the chief end-product of proteid metabolism, but that end is probably reached in several ways; so that probably a very large number of nitrogenous chemical substances make a momentary appearance in the body. Some of these fail to become urea, and either without or after further change make their appearance in the urine. But we do not know whether their appearance is accidental, the result of imperfect chemical machinery; or whether they, though small in quantity, serve some special ends in the economy. Perhaps sometimes, or with some of them it is the one case, at other times or with others it is the other case. . . . The evidence as far as it goes tends to show that the metabolism of proteid is very complex and varied, that a large number of nitrogen-holding substances make a momentary appearance in the body, taking origin at this or that step in the downward stairs of catabolic metabolism and changing into something else at the next step, and that the presence in various parts of the body and even in the urine, in small quantities, of so many varied nitrogenous crystalline substances, forming a large part of what are known as extractives, has to do with this varied metabolism. Possibly the transformations by which nitrogen thus passes downward take place to a certain extent in such organs as the liver and the spleen, which are remarkably rich in these extractives. But the whole story of proteid metabolism consists at present mostly of guesses and of gaps.

In this veil of mystery that surrounds the chemical transformations of the food-substances in the body there are today many rifts through which new truths have been brought to light. Uric acid is no longer associated with the metabolism of the simple proteins, but is recognized as the excretory end-product of the purins, a group of compounds distributed widely in nature, either free or combined as they are in the nucleoproteins of cellular tissues. By the exclusion of glandular material, like liver and sweetbreads, and of meat with its free hypoxanthin, the dietitian can reduce the production and output of uric acid in man at will. Here is one of the striking instances of where, through the newer knowledge of foods and metabolism, the physician has become a master of the chemical performances of the organism. The creatinin of the urine, provided that it is not reinforced by ingested precursors in meat, represents a story of the inner workings of the organism quite independent of the protein in the diet. The ammonia output is in a measure an index of the overproduction of acids in the body. Although by no means the only regulatory device whereby the neutrality of the blood and tissues is maintained in health, ammonia is nevertheless automatically furnished in conspicuous amounts when it becomes necessary to offset an impending acidosis. Hitherto the therapeutic procedure in such cases has been to furnish an alkali, commonly sodium bicarbonate, and thereby conserve the available supply of bases in the body from depletion. Recent studies have shown that a similar contribution of bases is afforded by a judicious selection of the dietary. There are foods which act as potential acids and others which function as bases in the organism. When burned up either in the laboratory or in the body-cells, they leave a preponderance of acid or base, as the case may be, in their ash. In this respect potatoes, apples, raisins, and cantaloupe, for example, are base-forming foods which depress the output of ammonia and increase the solubility of uric acid in the urine, as the experiments of Dr. Blatherwick in our laboratory have demonstrated; whereas meats, cereals and prunes (the latter with their content of benzoic acid) furnish acids in preponderance. Milk is intermediate in this respect. From the point of view here raised it is quite easy to accomplish as much with a liberal allowance of certain selected foods as with half an ounce of the familiar bicarbonate. To do this, however, implies that the physician must become as well acquainted with the properties of the foods as he appears to be with such novelties as amboceptors and complement, polyvalent vaccines and immune serums, salvarsan and epinephrin.

Turning attention to another group, the fats, the question must have arisen in the minds of many a physician as to why certain representatives of these foodstuffs have so long maintained a reputation for superior merit in connection with nutrition. There are several fluid fats which are quite as available, or even more easily procurable than is cod-liver oil. Yet this product continues to enjoy a vogue that cannot be dismissed as the mere result of advertising propaganda. Cod-liver oil was a favorite, particularly in the dietotherapy of children, long before the present era of catch-phrase circulars and illuminated billboards. Its supposed unique virtues have called forth varied attempts at explanation. At one time it was the trace of iodine found in cod-liver oil which was

believed to endow it with superiority over other fats like cottonseed oil and olive-oil having essentially the same physical properties and the same mixtures of glycerids, or fats proper. When this explanation no longer appeared tenable, the superior value of cod-liver oil was attributed to its ready digestibility. Lately Osborne and I have observed an unexpected efficiency in the product which is not shared by many other fats of similar superficial properties. We have fed growing animals (albino rats) on mixtures of isolated food substances including an abundance of fat in the form of commercial lard until, owing to the lack of some essential and as yet unknown ingredient of adequate dietaries, growth was checked. The replacement of a portion of the lard in the diet by cod-liver oil invariably brings prompt restoration of growth which continues uninterrupted until the adult stage is reached. Butter-fat and egg-yolk fat likewise contain a "growth-promoting" ingredient which appears to be more or less completely wanting in other dietary fats of both animal and vegetable origin. There is, for example, a marked difference between lard and the fat elaborated by the mammary gland. Whereas our experimental animals show symptoms of malnutrition with a cessation of growth and decline in weight at the end of three months on a diet including lard as the sole fatty ingredient, when either butter-fat or cod-liver oil were used there was no sign whatever of failure after a year or more of uninterrupted feeding on the same diet day after day.

It is well known that all of the naturally occurring fats, such as have just been mentioned, are complex mixtures of true fats in the chemical sense, along with other substances including lipoids, pigments and compounds more soluble in fat than in the watery mediums of the body. The lipoids, in particular—cholesterol, lecithins, cephalins—have come into prominence in connection with various reactions involved in serum diagnosis and such phenomena as hemolysis, narcosis and absorption. Though long recognized as a constituent of the nervous tissues and certain pathologic products such as gall-stones, cholesterol has remained a compound of unknown function until very recent times. At the present moment the consensus of opinion appears to be that cholesterol is not ordinarily formed within the organism of the higher animals, and that these are dependent on the food intake to maintain the essential supply thereof. If this be true the ultimate source must reside in constructive plants; and assuming occasional losses from the body, doubtless with the feces, the store of cholesterol can be kept intact in man only by renewal from a suitable dietary. Ordinarily, in the adult living on a ration of products derived from many sources, no difficulty arises, because compounds of the cholesterol type are widely distributed and presumably found in all cells; but it is quite conceivable that in individuals like growing children or patients living on a diet restricted in character a real deficiency of cholesterol may ensue. It is known that the hemolytic phenomena of the red blood-cells are related to their lipid content; and the therapy of the future may find a place for such substances as cholesterol, cephalin, etc., in the management of hemolytic anemias and other pathologic manifestations. Here, again, the intricacies of the diet cannot be overlooked by the intelligent physician of the future.

I have dwelt somewhat on the possibilities in respect to cholesterol and the growth-promoting components

of milk-fat, egg-fat and cod-liver fat because it affords an opportunity to emphasize the hitherto largely unappreciated importance of factors in nutrition which cannot be expressed in terms of the familiar protein, fat and carbohydrate or in calories of energy. These factors may be inorganic in some cases, as is instanced by the reputed rôle of iodine and the wide distribution and alleged significance of manganese, boron, silicon and other elements in animal tissues; they are frequently organic in character. To class these varied factors together under the euphonious designation of "vitamins," as has lately been done, does not render less obscure the deficiencies which the absence of them from the diet may entail; nor does it give any clue to the mechanism whereby growth may be promoted, metabolism stimulated, or deficiency diseases engendered. Not only in those admitted instances of diet deficiencies such as beriberi and scorbutus, but also in numerous other clinical and experimental types of malnutrition there is need for further research. The proverbial adherence of the medical profession to dogmatic statement must be changed. Its members must become eager to take up the current views, study the underlying data as well as they can, and watch the consequences. Let us welcome the day when the food market and the kitchen are taken into consideration by the physician as seriously as are the apothecary's shop and the fashionable spas.

If in all the foregoing little mention has been made of the carbohydrates in nutrition, it has been because, in a general way, more has been known about them for a longer time than is true of the other nutrients. Even among the carbohydrates the principle of specificity comes into play. The physiologic carbohydrates are the six-carbon sugars, such as glucose, levulose and galactose. Unless an ingested carbohydrate can be converted into this simple type of sugar in the alimentary tract, its nutritive value is distinctly impaired or entirely lost. For this reason, all attempts to introduce more complex sugars, dextrins or starches directly into the blood-stream, for prompt distribution to the tissues which need them, have failed. In experiments conducted in our laboratory, animals have received subcutaneous or intraperitoneal injections of cane-sugar or milk-sugar for weeks and months without acquiring the capacity to utilize so little as a single gram introduced in this way in an undigested form. Carbohydrates like inulin and the galactan of agar-agar or of Irish moss can furnish no energy to the human organism because it is unable to digest them, that is, to convert them into simple sugars. The possibility of nourishing an individual in some way other than by the oral path evidently depends on introducing the nutrients in the form of those units—the amino-acids, simple sugars and fats—which normally constitute the actual pabulum of the hungry cells.

Physiology has borrowed its methods largely from the sciences of physics and chemistry. It also has a fruitful method of its own, that of experiments on animals and man. None of these procedures can be dispensed with. They corroborate and supplement each other, and they serve to test the hypotheses which give the impetus to progress. The medical profession must insist on conserving for the physiologic sciences the opportunity to continue its studies untrammelled by the passing prejudices of those who fail to appreciate its motives.

18 Trumbull Street.

INTERMEDIARY PROTEIN METABOLISM*

OTTO FOLIN, PH.D.

BOSTON

The subdivision of protein metabolism into intermediary metabolism and tissue metabolism indicates that we to-day are in possession of a much more detailed and accurate knowledge concerning animal metabolism than was available a few years ago. The controversy between Voit and Pflüger and their followers of the past generation as to whether the protein of the food must be incorporated in the protoplasm of the tissues before it is oxidized was an unprofitable and useless controversy, because it was too far in advance of the experimental knowledge of that period. We still do not know the spatial relationship between protoplasm and food materials at the moment of oxidation. On the other hand, we no longer speak of protein metabolism as being an oxidation process at all in the sense understood by Pflüger and Voit. While protein materials like other carbonaceous food materials are of course finally oxidized in the body, we now believe that the nitrogenous foodstuffs first undergo changes and chemical transformations involving the loss of all protein characteristics before they are completely destroyed by the oxidation processes involved in the production of heat and energy. Through the investigations of Kutscher (1898), and more recently of Abderhalden and his associates, it has been made clear that protein materials are completely decomposed into simple crystallizable products, the amino-acids, as a result of digestion. This discovery is fundamentally important for it has necessitated a complete revision of the earlier ideas and doctrines as to the nature of the metabolic processes involved in the utilization of protein as food. The old, burning question as to whether protein must be incorporated in the living tissue protoplasm before it is oxidized we now know was a false question, because the food protein has been altered beyond recognition even before it leaves the digestive tract and many of us no longer believe that protein as such is ever oxidized in the body.

The discovery that protein materials are split up into the simplest possible component parts during the digestion suggested two new fields for metabolism investigations. The first of these is the question as to whether simple amino-acids can be substituted for ordinary food protein, and which if any of the amino-acids are most indispensable for the maintenance of the animal organism. Much interest and important work has been done in this field, and it has become quite clear that some amino-acids are indispensable while others appear to be less necessary constituents of the food. The importance of all these data to the science of metabolism, if not to medicine, is self-evident in view of the fact that practically all the amino-acids can be manufactured. The second metabolism problem which required renewed investigations when the deep-seated character of protein digestion became clear concerns the subsequent history of the digestion products, and inasmuch as my own investigations lie in this field, I shall confine myself to a discussion of this problem.

Formerly it was generally believed that protein materials were but little altered by the digestion, and the protein of the food was supposed to pass into the blood-stream without any material alteration. Since no peptones were found in the blood the peptones formed during the digestion were supposed to be regenerated into more complex albuminous materials while passing through the mucous membrane of the intestinal wall just as fatty acids and glycerin are believed to be transformed into neutral fats during the absorption. This hypothesis seemed plausible, because it agreed with the experimental observations and because the animal organism was supposed to be dependent on the complex kind of proteins found in the blood. Many investigators, including Kutscher and Abderhalden, adhered to this explanation of what happens to the nitrogenous food in the intestinal wall even after it became certain that amino-acids and not peptones were the chief end-products of the digestion. Many physiologists, however, abandoned the protein regeneration hypothesis about ten years ago. To them it seemed highly improbable that the proteins should first be completely split up into amino-acids only to be immediately recombined into albumin and then again immediately broken down so as to give the urea, the elimination of which is greatly increased three or four hours after the intake of protein food.

In place of the protein regeneration hypothesis these dissenting physiologists assumed that the transformations of nitrogenous materials which take place in the intestinal wall are of a destructive rather than of a constructive character. Just as the digestive ferments convert the proteins into amino-acids within the digestive tract, so by a continuation of the digestive or hydrolytic processes most of the amino-acids immediately lose their nitrogen while passing through the intestinal wall and the liver. The prompt formation of urea, the supposedly large amount of ammonia in the portal blood, and many other features of the nitrogen metabolism were explained in a fairly plausible fashion by this hypothesis.

There remained, however, another possibility, namely, that the intestinal wall does nothing to the amino-acids but simply lets them through. From a theoretical aspect, this point of view has been the most plausible, and notwithstanding numerous early failures, the efforts to prove that the amino-acids are absorbed from the intestine without change have been continued, and now there is no longer any doubt about the fact that the end-products of protein digestion, the amino-acids, are quickly and easily absorbed. In fact, the speed of the absorption and the speed with which the amino-acids are distributed to all the different tissues in the body is one of the reasons why the earlier investigators failed to find the digestion products in the blood.

By means of the quantitative colorimetric methods devised in my laboratory, by means of Van Slyke's micro method, and by means of Abderhalden's qualitative ninhydrin test it is now easy to show that the amino-acids are absorbed. We have therefore now not the slightest reason for believing that the amino-acids formed during the digestion undergo any change while passing through the walls of the intestine.

The essentials of the story of protein digestion and absorption appear to be very clear indeed, and can be stated in two or three sentences. In the stomach the greater part of the protein is dissolved and much of it is converted into albumoses and peptones. In the

accurate method of indirect calorimetry. The box is ventilated by a rotary fan which sucks the air out of one end of the chamber, drives it through a bottle of sulphuric acid to remove all moisture, then through a bottle of soda lime to remove the carbon dioxide and finally returns the same air, absolutely pure and odorless, to the other end of the calorimeter. As the patient uses up oxygen, this gas is supplied automatically from a small tank. By weighing these various bottles and tanks at the beginning and end of each hour it is a simple matter to determine the carbon dioxide produced and the oxygen consumed. Knowing the relative proportions of these and also the nitrogen of the urine one is able to calculate with great accuracy the grams of protein, fat and carbohydrate oxidized by the patient during that hour. Knowing the heat produced by the oxidation of 1 gm. of each of these substances it becomes a simple matter to calculate the total heat production.

The two methods of direct and indirect calorimetry agree within 5 per cent. in about three-fourths of the experiments, and in many cases the figures are almost identical as is shown in Chart 1, that of one of the

hours after the last meal. It will be seen in Chart 2 that if we express the metabolism in terms of calories per square meters of the body surface per hour, the results will group themselves close to the average figure of 34.2 irrespective of the body-weight. The dotted line represents the average of forty-nine normal controls studied by various types of apparatus in many laboratories. It is evident that the level is the same for persons whose weights are between 40 and 50 kg. (from 88 to 110 pounds) as for those whose weights are between 60 and 70 kg. (from 132 to 154 pounds). On the other hand, if we express the results in terms of calories per kilogram per day we have a line of averages which falls steadily as the weight increases. In order to have a single base-line which need not be changed for persons of varying weights we therefore compare all our results with the average normal figure of 34.2 calories per square meter per hour.

While the metabolism of a given individual remains fairly constant for years, there may be a variation among normal men of 10 per cent. above or 10 per cent. below the average. Further study will perhaps show even a greater variation. The metabolism is

Chart 2.—Basal metabolism of normal men from fourteen to sixteen hours after the last meal. Columns represent calories per square meter per hour produced by subjects in bed calorimeter. Horizontal line drawn at 34.2, the average. Interrupted lines represent averages of 49 normal controls studied with various types of respiration apparatus, arranged in five groups according to weight. Dotted line shows the results expressed according to surface area. Dash line represents the same 49 controls with the results expressed in terms of calories per kilogram per day.

normal controls. In the total of all the experiments so far calculated, involving the measurement of 23,000 calories, the two methods agree within 1.6 per cent. As yet no disease has been found in our somewhat limited series of observations in which there is any consistent disagreement between the two methods. This is a matter of considerable import, since the previous work in the study of the heat production in disease has been done almost exclusively by the method of indirect calorimetry. The agreement of the two methods shows that the calculations by indirect calorimetry have not been vitiated by any profound and unsuspected changes in the intermediary metabolism.

It is comparatively easy to determine the total metabolism but difficult to find the exact normal figure with which to compare the results. We have measured the basal heat-production of a number of normal persons of varying weights and have grouped them with the normal controls examined by Benedict in his bed calorimeter, all determinations being made on individuals at complete rest, from fourteen to sixteen

increased in childhood, diminished in old age, and probably depends, to a great extent, on the nutrition of the body and the mass of active protoplasm. Nevertheless, Rubner's law that the metabolism of different individuals and different species of animals is proportional to surface area does hold good within certain limits. These limits may be wide when we try to compare the metabolism of babies, guinea-pigs, athletes and fat men, but, as we have shown above, the limits are narrow for a group of men of approximately normal build.

Voit and Rubner demonstrated the fact that the taking of food raised the heat production, and the term of specific dynamic action was applied to this phenomenon. The cause of this was little understood until Lusk² studied the matter in great detail, making hourly determination of the heat production of dogs in the small Cornell calorimeter. His work on dogs

2. Lusk: Animal Calorimetry. Papers II, III, V, VI, Jour. Biol. Chem., 1912, xii, 349; xiii, 27, 155, 185; Cause of the Specific Dynamic Action of Protein, Arch. Int. Med., December, 1913, p. 485; The Specific Dynamic Action of the Foodstuffs, this issue, p. 824.

has been duplicated on normal men as nearly as the human stomach will permit, but, of necessity, the amounts of food are relatively smaller and the increases in heat production distinctly less marked. Chart 1 shows the basal metabolism of control D and the effects of glucose and protein meals. The increase after glucose amounts to from 8 to 10 per cent. and after protein to 12 per cent.

Chart 3.—Typhoid fever, "Morris S." Basal determinations, B connected by dash line. N, protein meal. D, from 100 to 200 gm. of glucose. Results expressed in averages.

Since the time of Voit and Pettenkofer a great deal of work has been done on the subject of the respiratory metabolism and total heat production in disease. Magnus-Levy³ established the fact that in exophthalmic goiter the energy requirement was greatly increased even to a point as high as from 50 to 70 per cent. above the normal and showed that in cretinism and myxedema the heat production might be as low as from 45 to 50 per cent. below the normal. Kraus,⁴ Grafe,⁵ Rolly⁶ and others demonstrated that in typhoid fever the metabolism was raised to from 30 to 40 per cent. above the normal. Grafe⁷ has recently shown that the heat production is low in certain stuporous conditions and increased in lymphatic leukemia and cancer. The total heat production in diabetes has been studied by many observers with varying results, but Benedict and Joslin,⁸ using the calorimeters in Boston, have shown that in cases of severe diabetes with acidosis there is an increase in metabolism.

The study of the metabolism in typhoid fever and the effects of the high-calory diet was begun in Belle-

vue Hospital in 1911 in association with Dr. Warren Coleman. The small Benedict apparatus was used and the calculations were made according to the method of indirect calorimetry. A summary of the results will be presented by Dr. Coleman⁹ in another Section but it may be stated that the heat production of the patients was not raised by the administration of large amounts of food during the height of the fever. The matter seemed so important that it demanded investigation by the use of the calorimeter.

Observations were therefore made on nine typhoid patients during the course of the fever and convalescence. The first part of the results on one patient, who was in the calorimeter twenty-two times, is shown in Chart 3. This patient enjoyed the work with the calorimeter. His original infection was by no means mild and he had one relapse which was severe and a second relapse which scarcely interrupted a rapid convalescence. Throughout the disease he was so well nourished that his weight remained practically constant.

It will be noticed that during the fever his total metabolism was from 40 to 50 per cent. above the average normal and that it was scarcely increased at all on the days when the observations were made shortly after the ingestion of 100 gm. of glucose or 64 gm. of protein. A study of the nitrogen in the urine in this and three other cases shows that the percentage of calories derived from protein during fever when the patients were fasting was seldom raised above the upper normal limit of 20 per cent., although one patient early in his disease derived 28 per cent. of the calories from protein.

As the temperature falls the total metabolism diminishes and the percentage of calories derived from protein drops to 10 or 15 per cent. During convalescence heat production may be from 20 to 30 per cent. above normal, and at this stage glucose and protein exert as great a specific dynamic action as in health.

Chart 4.—Cretinism results expressed in hourly periods. Thyroid-extract treatment begun two days before last observation.

The diseases of the thyroid gland have been studied with particular interest since the level of the total metabolism seems to be the best index of the activity of the thyroid secretion. In one cretin who was 36 years old but had the mental and physical development of a child of 8, the total energy requirement was from

18 to 25 per cent. above the normal but was raised almost to the normal on the third day of treatment with thyroid extract (Chart 4). The specific dynamic action of food was normal in this patient.

A series of seven patients with exophthalmic goiter were studied before and after treatment in an effort to guide the therapeutics in this disease, which is remarkable for the number of "remedies" that do not give relief. Luckily we were able to show some beneficial effects of treatment, although good results were obtained by rest and careful feeding alone. One patient, who had shown moderately severe symptoms for one year, was studied over a considerable period of time. If we look at the results as expressed in Chart 5, we notice that, in marked contrast to the cretin, the metabolism is 80 per cent. above the normal, falling to 60 per cent. on rest and good food. Von Noorden¹⁰ has stated that the specific dynamic action of food and especially of meat is increased in fever and in exophthalmic goiter. We have seen that this was not the case in fever and it was evidently not true

Chart 5.—Exophthalmic goiter. Results shown in hourly periods. Dash line connects basal determinations. Dot-dash line represents average pulse during the period of observation in calorimeter.

of this patient, since his metabolism was not raised even so much as that of a normal man by glucose, casein and meat. After treatment by Dr. S. P. Beebe with his antithyroid serum, there was a distinct improvement in the man's condition and fall in the metabolism. After the first month there was a rise in metabolism to its former level but the general improvement continued perhaps, however, at a slower rate.

A young woman who was up and about, though not quite able to continue her work as trained nurse, showed the extraordinarily high metabolism of 92 per cent. above the normal. After ligation of the arteries by Dr. John Rogers, the metabolism fell to 60 per cent. above the normal and the patient's condition was distinctly improved.

One young woman with a mild case of the disease showed a marked rise in metabolism four days after

ligation of the four thyroid arteries, indicating that the operative procedure had temporarily increased the activity of the gland. Later there was distinct improvement in her general condition and a fall in the heat production to its former level.

Other conditions have been studied in a few cases and while the results need confirmation, they are suggestive and may lead to a better understanding of the various factors which influence the heat production in disease. One patient with splenic anemia, whose hemoglobin was 25 per cent., had a metabolism 11 per cent. above the normal; another with pernicious anemia for which a splenectomy had been performed, showed an increased metabolism amounting to 20 and 26 per cent. above the normal, while his hemoglobin was only 20 per cent. This confirms the older work, which demonstrated that there is no diminution of oxidation as a result of the low percentage of hemoglobin. In a patient with nephritis a change in blood-pressure from 195 to 160 caused absolutely no change in heat production. One man with acromegaly had a metabolism 18 per cent. above the normal, another with

symptoms of deficiency of the secretion of the posterior lobe of the hypophysis gave results sometimes high and sometimes normal but he was so stupid that he made a very unsatisfactory subject. Another man with malaria was studied at the height of his fever, and also six days later when his attacks were cured. With a temperature of 104 F. the metabolism was 83 per cent. above the average, with a normal temperature 21 per cent. A patient with auricular fibrillation, mitral stenosis and greatly enlarged heart but without orthopnea, was observed three times lying flat on his back and twice propped up with a back-rest. We were astonished to find the metabolism which was normal when he was propped up was 8.5 per cent. higher when he was lying down and were even more surprised to observe the same phenomenon in the only normal control we studied in this posture.

The increases due to fever, hyperthyroidism and the like, are probably small compared to the increase caused by muscular work in delirium tremens or convulsions. Even slight restlessness or mild excitement causes a rise in heat production which is distinctly appreciable in the calorimeter.

In conclusion, it may be well to emphasize the fact that the nutrition of a patient depends absolutely on the relationship between his energy production and his food-supply. If the organism fails to obtain food from without it will draw on its own glycogen stores, fat depots and supplies of body protein.

129 East Seventy-Sixth Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF MENDEL, FOLIN, LUSK AND DU BOIS

DR. S. J. MELTZER, New York: For more than thirty years I have been moving on the periphery of laboratory work on one side and clinical medicine on the other side. Well do I remember the wide gulf which separated the laboratory men from the men in clinical medicine. To-day we have heard four men telling of their work in the sciences of medicine and telling it to a large audience, consisting, as far as I can judge, chiefly of men who are active in the practice of medicine. There are reasons for more congratulations. We heard to-day four men telling of their own original work in the scientific part of medicine. In the times gone by the laboratory man was satisfied to discuss work which was done on the other

10. Von Noorden: New Aspects of Diabetes, New York, E. B. Treat & Co., 1912, p. 20.

side of the Atlantic; to-day the scientific men in Europe take profound notice of the work done in this country. Again, in the past, laboratory men used to be proud of the fact that they had nothing to do with the practice of medicine. To-day the laboratory men are anxious to do work in fields which are of special interest to the practitioner. Mendel speaks of "gaps and guesses" in scientific reports. I am certain that a thousand years from now "gaps and guesses" will have a prominent place in scientific reports. The gaps which we fill out by our investigations, we do by means of guesses, and they reveal to us new gaps. Liebig's theories are mere guesses for us to-day, to be forgotten. But they were instrumental in filling up many gaps by facts. Theories are of value because they help us to discover facts, and as long as they can do that they are still of value to us. I wish to say to Dr. Mendel that the amboceptor theory of Ehrlich, of which he spoke somewhat disparagingly, has brought out thousands of important facts in immunity, and is still capable of bringing out new facts. I am still more sorry that Dr. Mendel spoke in a somewhat disparaging manner about salvarsan. The synthetic creation of such a specific substance like salvarsan is one of the most wonderful discoveries made in recent times in the sciences and practice of medicine. The discovery by Dr. Mendel in conjunction with Osborne, that butter does contribute to the growth of rats, while lard does not do it, is perhaps the best he has ever made. This discovery was made by the empirical method; they do not tell us on what hypothesis they found it; neither what is the nature of the "vitamin" which differentiates lard from butter. We call this method, when used in science, the inductive method. But it differs from the empirical method which the physician uses merely by the application of criticism. Criticism is here necessary to differentiate the coincidental from the causal connection. Here the physician must learn from the scientist. A patient may get better merely while he is taking a drug and not because he takes it. But there is one point which the scientist has to learn from the physician; it is the principle of *non nocere*: be sure that you do not do any harm. For instance, the knowledge that the minimum diet is of no perceptible immediate harm to animals is no evidence that it will be of no harm, acute or chronic, to human beings. Neither do we know that infants will behave like rats regarding the difference between butter and lard.

DR. F. M. POTTENGER, Los Angeles, Cal.: Does this difference in the absorption of fats apply to all animals alike, whether herbivorous or carnivorous and also to man?

DR. E. P. JOSLIN, Boston, Mass.: I should like to ask Dr. Lusk if he has an explanation to offer as to why the metabolism is not increased by food in typhoid fever?

DR. ALLAN EUSTIS, New Orleans: I wish to discuss that part of the paper in which Dr. Mendel refers to the amins formed by the putrefaction of the several amino-acids in the intestinal tract. This has a broad practical application in clinical medicine, as each of these amins has its own specific physiologic action, just as the amins from the vegetable kingdom, represented by the alkaloids strychnin, morphin, etc. Tyramin (para-oxyphenylethylamin), which is yielded by tyrosin on putrefaction, is capable of raising the blood-pressure in a dog from 110 to 250 mm., while in man it has produced a rise to 180 mm. I have made application of this fact in treating nearly five hundred cases of arterial hypertension, in which the systolic blood-pressure has been kept down to 140 or 150 mm. by dietetic means alone. It must be remembered that caseinogen of milk yields 7 per cent. of tyrosin on digestion which contra-indicates milk as an ideal food in this condition. Inasmuch as all animal proteins yield large amounts of tyrosin they are also contra-indicated, while the best results will be obtained from a cereal and fruit diet. The clinical application of the formation of histamin (beta-imidazolylethylamin) from histidin can be made in the treatment of bronchial asthma and urticaria. When injected intravenously, this amin causes violent bronchial spasm similar to an attack of asthma, while when rubbed vigorously into the skin a solution of 1:1,000 causes a typical urticarial lesion. Along dietetic lines alone, I have been able to give relief in 168 cases of bronchial asthma and twenty-six cases of urti-

caria, some of the asthmatics having had the disease for twenty years. A diet for these conditions should be based on the fact that the yield of histidin in the more common types of proteins is: hemoglobin, 10 per cent.; sturin, 12 per cent.; caseinogen, 2.5 per cent.; 2.5 per cent., and gliadin, 1.4 per cent. Articles of diet which yield little or no histidin may be allowed. It must not be concluded that all cases of arterial hypertension are due to the absorption of tyramin from the intestinal canal, nor that all cases of asthma and urticaria are due to histamin absorption; but it must be admitted that these amins have a decided practical bearing in clinical medicine and must be reckoned with.

DR. DOUGLAS HEAD, Minneapolis: I should like to ask whether any observations have been made as to the effect of butter feeding on heat production in long, thin-chested, enteroptotic persons as compared with those of short, stocky build?

DR. A. J. CARLSON, Chicago: I think you all know that in this particular field America has made a distinct contribution to science. I have been impressed by the interest taken in this symposium by the members of the American Medical Association. If there is anything new of importance in the practice of medicine it is this modern work in nutrition. And it is evident that when the laboratory men really have something to say the clinical men will listen.

DR. VICTOR C. VAUGHAN, Ann Arbor, Mich.: Will Dr. Folin explain one point on which he did not touch? We recognize that in enterodigestion the proteins are split into amino acids. Dr. Folin holds that the amino acids are absorbed directly into the walls of the intestines, a view held by many others. The proteins are carried to each cell and each cell utilizes what is suited to its needs. This I dare say is all right. One point which he should explain, is important. There must be some synthesis of amino acids in the body. The sero-albumin and globulin in the blood are specific proteins, each coming from different sources. These are taken into the blood, and by the brilliant work of Folin and others we are now able to demonstrate the presence of amino acids in the body. Now there must be some synthesis somewhere. We must not lose sight of the fact that enterodigestion is not the only form of digestion that occurs in the animal body. There is in the blood a digestive process as much as in the intestines. A proteolytic ferment is present in the blood, a trypsin and an antitrypsin, and the understanding and the adjustment of the relation of these two factors is one of the great problems of physiologic chemistry.

DR. OTTO FOLIN, Boston, Mass.: Undoubtedly all will agree that the question asked by Dr. Vaughan is too much for even a laboratory worker to attempt to answer. The question that Dr. Vaughan has really asked is "How are tissues formed?" I have discussed the subject of the destruction and the history of protein in the body from the point of view of food and from that of destructive metabolism. The matter has two aspects, a destructive and a constructive; the constructive or the synthesis of protein is synonymous with the formation of tissue itself and is far from the transformation of amino acids into urea. There are two distinct aspects of metabolism. I considered only the destructive processes, the breaking down, and these only as produced by the class of agents sometimes known as enzymes. Frequently enzymes are of the destructive variety. They are hydrolytic and there is a degradation form of reaction. As to the difference between the enzymes and the proteins and the subject of hydrolytic and synthetic ones, all can discuss this part of the subject as well as I can.

DR. GRAHAM LUSK, New York: Replying to Dr. Joslin's question, "Why is there no increased metabolism in typhoid fever after giving an excess of food?" I would call attention to the fact that under normal conditions the basal metabolism is measured by the heat production of a subject whose gastro-intestinal tract is free from food and who is living at an environmental temperature of 26 C. (78.8 F.). If, however, the temperature be lowered there is an increase in the heat production although, under these circumstances, the ingestion of food may now produce no specific dynamic action. Furthermore, it is known that, if the metabolism be

increased to a certain point through carbohydrate, the addition of amino acids to the diet may cause no further increase in metabolism. Likewise, it should be remembered that in fever the protein metabolism can never be reduced to the low level present in the normal person, so that when amino-acids enter the organism under these circumstances they tend merely to replace those already breaking down in large quantity. It is therefore apparent why in fever the metabolism may have already been lifted to such a level that ingestion of food causes no further increase.

DR. EUGENE F. DU BOIS, New York: A comparison of the metabolism of enteroptotic persons with that of short, stocky men would be interesting, but we have had no opportunity of making such observations. From a theoretical consideration it would seem that the enteroptotic, undernourished persons would have a rather low metabolism, and it would seem that muscular persons would have the higher metabolism. Yet from clinical observations it appears that the enteroptotic persons have the greater energy requirement. We have at times tried to guess the actual heat production of individuals and groups of patients but have found that sometimes we were as much as 25 per cent. from the true figures as determined by the calorimeter.

COMMON ERRORS IN GALL-TRACT SURGERY*

C. E. RUTH, M.D.
DES MOINES, IOWA

An operative technic which gives a low mortality may be far from perfection, especially when relief is not obtained by the patient from the trouble for which the operation was done, or when other calamities must be endured by the patient which are a direct result of the operation.

In no class of operative procedures for non-malignant conditions are secondary operations required in so large a percentage as in those done on the gall-tracts. In no class of abdominal work is the temptation greater for inefficient or incomplete work, and in none is complete work more difficult than that encountered in many of these cases. Stones in the common duct, at or near the lower end, are found and removed successfully by only a very few operators. The amateur aspirant to surgical honors and perquisites can safely drain a large readily accessible gall-bladder, and if perchance he find a stone, that is the end of the matter with him as covering all requirements and obligations.

I am reminded that once I opened the abdomen, after having done several thousand abdominal sections, and examined carefully for gall-stones and did not find any, but at post-mortem four weeks later seventeen stones were found in the gall-bladder and one in the ampulla of Vater.

At another time when doing an abdominal section for other causes I confirmed by direct palpation a previously made diagnosis of gall-stones, but six months later when the patient came to operation for removal of the gall-stones, I could not even find a gall-bladder, but encountered pancreatic calculi amounting to over a thousand grains, forming a complete cast of the entire pancreatic duct system. These I was able, with great difficulty, to remove successfully through incisions in the pancreas after opening through the gastro-

hepatic fold of mesentery, which enabled me to reach the affected organ after displacing the stomach downward. I am convinced that no operation for relief of supposed pathology in the biliary tracts is completed without an examination of the pancreas.

The large number of secondary gall-tract operations is due to errors in diagnosis, failure to remove all calculi, allowing the drainage to close while infection is still active, and failure to remove the gall-bladder in all cases in which there is not a free communication or

Fig. 1.—Author's technic. Method of incising gall-bladder, the fundus being grasped by flat forceps.

passage in both directions through the cystic duct, provided the common duct is freely patent.

Bile may often pass quite readily from the common duct into the gall-bladder, but returns with much difficulty or not at all by the ordinary contractions of the gall-bladder. In such cases permanent drainage or removal of the gall-bladder can alone afford permanent relief. The removal of the gall-bladder or its entire mucosa down close to the junction with the common duct is imperative to make relief permanent and obviate drainage annoyance.

In many cases of secondary operations following gall-bladder drainage I find the pyloric end of the stomach, first part of the duodenum, gall-bladder, liver and abdominal wall one continuous mass of adhesions. The result is that such a patient is never free from discomfort by pain, dragging, impaired stomach motility and often partial obstruction of the pylorus, which causes gastric dilatation with its accompanying entrapment. Unnecessary and rough handling of abdominal viscera during operation, unnecessary wiping of endothelial surfaces with gauze (especially dry gauze), extensive and unnecessary spreading of infection over clean territory and making no intelligent use of Nature's preventive material at hand are the principal causes of these deplorable and preventable com-

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

plications. Relief of these patients from the operative complications requires much more skill and represents much more danger and difficulty than to deal properly with the original trouble.

In no case should the gall-bladder be attached directly to the abdominal parietes in drainage operations, because of the traction and dragging so liable subsequently to torture the patient. In all cases the drainage tube placed in the gall-bladder should be large and the margins of the gall-bladder should be inverted so that when the tube is removed the margins of the inverted gall-bladder opening at once collapse and promptly close the drainage (Figs. 3 and 4). However, should the bile show the presence of infection (by culture examination) a tube must at once be replaced and drainage maintained until the infection is under control.

The first or original tube placed in the gall-bladder must be secured by a catgut suture placed in the gall-bladder which will hold at least eight days (Fig. 4). The tube should lie free in the abdomen from where it leaves the gall-bladder to the point where it is to pass through the parietes, and at the latter point it should pass through a stab wound made on purpose for it, and should *never* pass (as is the almost uni-

majority of cases primary union can be secured, thus entirely eliminating other preventable complications, namely, suppuration of any part of the main wound, prolonged convalescence and a large percentage of hernias, for which there is *slight, if any, justification* (Fig. 6).

The use of the median incision for operating in all gall-tract cases will make it possible at the same time to deal with any other condition or complication in the abdomen through the same, or an extension of the

Fig. 2.—Opening in fundus spread, allowing ready access to the interior of the gall-bladder. Method of placing the first row of sutures, and the prepared drainage tube are depicted in the upper corner of the illustration.

Fig. 3.—Drainage tube *in situ*, and held by the first row of sutures.

same, incision, while it almost removes the temptation to use the main wound for drainage instead of the stab, say 2 inches to the right, which will give vastly better drainage, particularly with the patient lying on the right side. The time-honored incision through the rectus, straight or bayonet, is much more vascular than the median or near median incision, causing some degree of annoyance in operating, and when anything but a simple drainage of a readily accessible, distended gall-bladder is done, requires enlarging to such a degree that more or less sectioning must be done of the nerve supply to the abdominal wall and rectus with permanent sensory paralysis of a portion so that as one patient expressed it, "I am unable to tell whether I am feeling my own abdomen or some one else's except by sight," to say nothing of increased danger to hernia from imperfect motor and nutritive muscular innervation as well as liability to infection from drainage contact with the line of incision. Many gall-tract cases require appendectomy, and in women often attention to the uterus or adnexa as well, in which case the median incision or an extension of it enables all to be done through the one incision with no necessity for any complication whatever arising from such extension and with no added operative difficulty. Any gall-tract operation can be done quite as well, and if complicated much better, through the median incision.

versal custom) *through the main wound* (Fig. 5). The protruding end of the tube should then be connected to a drainage tube long enough to reach a safe distance from the patient (better attach it to the bed rail), where it enters a bottle containing 2 or 3 ounces of 10 per cent. alcohol-carbolic solution, into which the end of the drainage tube is passed so that the end of the tube is kept all the time below the surface of the liquid. This plan enables the main wound to be closed entirely and to remain dry, and in the vast

Removal of the gall-bladder is seldom difficult if done at the first operation under proper technic or as a secondary procedure, provided infection and trauma have not caused extensive and dense adhesions.

In my own work I prefer to remove the gall-bladder by first clamping the cystic duct between strong forceps close to its junction with the common duct, and then divide the duct between the forceps. The forceps placed on the cystic duct close to the common duct must be made to grasp the cystic artery also. The gall-bladder is then readily separated from the under surface of the liver and entirely removed almost without hemorrhage. In other cases in which adhesions are dense and it is difficult to find and follow the cystic duct, though the gall-bladder is accessible, I have found it easier and better to follow the gall-bladder and cystic duct downward from the fundus, splitting the bladder and duct all the way down. In this way I have found it easy to trace and the hemorrhage was

An additional precaution is the placing of an angular or curved glass tubal connection in the drainage tube which passes through the abdominal wall and connecting the other end with a long tube which is passed into the drainage bottle; and by leaving 1 or 2 inches of the glass connection exposed, the presence or absence of drainage can be at once noted on inspection.

In obstruction of the common duct from inoperable carcinomatous conditions, it is wise to make an anastomosis between the fundus of the gall-bladder and the highest point available in the small intestine.

A small Murphy button properly placed makes an admirable anastomosis connection, though I think it wise to attach a string and piece of gauze to the intestinal side to exert traction on the button and prevent its sticking or perchance falling back into the gall-bladder.

When the gall-bladder is not available as above for switching the biliary current into the intestinal tract,

SUMMARY OF OPERATIONS ON THE GALL-TRACT

Case	Age	Stones*	Operation	Complications	Infection	Remarks
1	71	+	Primary	Infarcts in liver profoundly septic	Not determined	Condition critical; pus; extensive adhesions; patient died†
2	39	+	Secondary	Gastrojejunostomy	Colon bacillus	Extensive adhesions

* In this column + indicates stones, and — no stones. † This was the only death in this series; the other patients recovered. ‡ Mrs. H. L. had one previous cholecystotomy operation for the same condition and required two subsequent operations before recovery was complete and permanent. The last consisted of cholecystectomy. § Mrs. L. E. S. had three previous abdominal sections which were accountable for the ventral hernia. Those three previous operations had been done by the same operator. Conditions unknown to the writer. || The ventral herniotomy complication in this case (Mrs. M. C.) resulted from an abdominal section done by the writer two years previously when an ovariectomy was done for removal of a cyst containing 3 gallons of pus, and her temperature was 103 under profound sepsis.

slight. When the termination of the duct is found, it and the gall-bladder may be dealt with as above, or the mucosa of the cystic duct may be ligated close to the mouth of the duct, all the balance of the mucosa removed and the two outer coats closed over all, leaving a smooth peritoneal surface. This is as effective as removal and it as safely eliminates the gall-bladder as a subsequent annoyance as does the other plan.

A good-sized drainage tube should, however, be sutured in the bottom of the wound in contact with the point of greatest probability of bile leakage, and the patient should lie on the right side for the first forty-eight hours so that there will be free down-hill drainage through the tube to the outside of the body and no tendency to damming back or overflow through the general peritoneal cavity, but an open canal and no back pressure.

and the common duct is largely lost by removal for malignancy, a soft rubber drainage tube may be inserted into the hepatic end of the common duct and secured by encircling catgut ligature and suture while the other end is inserted into the duodenum passing through the intestinal coats diagonally for 1/2 to 3/4 inch. It should have a silk or linen thread attached to gauze in the intestine and fastened to the lower end of the tube. This will make light traction on the tube in all downward peristalsis, and will finally free the rubber, which will pass with the fecal current, but not before Nature's kindly offices have formed a mucous- and endothelial-lined tube or new duct to convey bile into the intestine.

The function of the gall-bladder being to regulate the tension of the gall circulation and not at all for storage purposes readily accounts for the relative

impunity with which it may be removed and the patient suffer no marked inconvenience in its loss.

Avoidance of a return to the old habits of life which caused the original gall-tract infection will usually prevent a return of the conditions which necessitated the first operation, provided the operation be properly done or the patient's condition be such as to warrant a completed operation.

The time has long and forever gone when we operate on the gall-tract simply to remove stones. Recently I drained a gall-bladder for an infection

Fig. 4.—Second row of sutures in place and tube ready for inversion into the gall-bladder. Note the suture passing through the tube, insuring against dislodgment by undue traction or other accident. (The suture ends have not been tied and clipped.)

which was only four days old and found that we were dealing with a most intensely vicious, primary, pure streptococcic infection. The progress of this case, however, was favorable until the tenth day when a pneumococcic infection caused complete consolidation of the entire right lung. The latter complication taxed the patient to the utmost and made it impossible to avoid infection of the main wound, which is a rare occurrence in our work, though a good recovery was made.

Three cases are of sufficient interest, I think, to justify reporting in some detail:

CASE A.—Mrs. L., patient of Dr. Johnson, Alden, Iowa, was operated on about six weeks before she came into my hands, and drainage of the gall-bladder was done, but no stones were found. She was first seen by me Nov. 8, 1912, and operated on in Iowa Falls. She had obtained no relief from the previous operation.

Finding the pyloric end of the stomach and the first part of the duodenum firmly attached to the anterior abdominal wall, I released them and re drained the gall-bladder. Relief was prompt and continued so long as the drainage was maintained, but pain returned at once when the drainage of bile ceased.

She returned to me for operation, Feb. 3, 1913, at which time, dreading to remove the omental graft which I had placed to prevent the duodenum and stomach from uniting to the abdominal wall, and not enjoying the prospect of an enucleation of the gall-bladder because of the adhesions which I knew to be extensive and dense, I decided to drain permanently the gall-bladder into the nearest and most readily accessible part of the intestinal tract; this happened to be the hepatic flexure of the colon.

The anastomosis was made with a small Murphy button with string and gauze in the intestine attached to the bottom. Recovery was without incident save that the button was never found, and she was absolutely free from pain and discomfort for five months, when the pain returned as before.

Examination showed that the cholecystenterostomy anastomosis had practically closed so that drainage of bile into the colon from the gall-bladder was no longer free, and the gall-bladder was found distended with bile which had become sufficiently stagnant within the cystic duct to begin the formation of calculi on a mucous cholesterol precipitate. The gall-bladder was accordingly removed after sectioning and permanently and carefully closing the former attachment to the colon. This plan offered the only apparent hope of permanent relief because the cystic duct patency permitted of tolerably free passage of bile into the gall-bladder but would not allow it to return readily by the same route.

CASE B.—Woman, referred by Dr. Will G. Walker, Corydon, Iowa, was operated on in April, 1910, and had two gall-

Fig. 5.—Showing position of parts after the tube has been inverted and the free end brought externally through a stab wound. Generally a stitch of silk-worm gut is placed through the skin edges and tube, again insuring against dislodgment of the tube by traction.

stones removed and some work done on the pelvic organs. March, 1911, she was operated on and another drainage of the gall-bladder was done. Neither operation gave any relief from pain or daily vomiting. She was first operated on by me Dec. 13, 1911, for a small inguinal hernia on the right side. Following this herniotomy she did not vomit for five weeks. Then vomiting returned and was as bad as before.

June 24, 1912, she returned for relief from pain and vomiting. Roentgenoscopy revealed dilatation and ptosis of the

greater curvature of the stomach. Impaired motility of the stomach was believed to be due to adhesions. Opening the abdomen disclosed a mass of adhesions so dense and extensive that in the patient's enfeebled condition I lacked the courage to separate them and chose the easier operation, namely, a posterior gastrojejunostomy without loop, in the hope that better drainage of the stomach would control the pain and vomiting. Recovery was prompt and she rapidly gained in flesh and strength, but within a few weeks occasional vomiting and some pain returned, and within five months it was as bad as ever, though on a dry diet she would

Fig. 6.—Showing arrangement of external drainage system. Skin about median wound remains slightly discolored from iodine stain. Note relation of stab wound to median incision, and the glass connection (siphon drain) between drain proper and rubber tubing. Bottle, containing alcohol-phenol solution, should be lower than depicted, thus obviating all danger of kinking the tube at the neck of bottle.

occasionally gain quite a little for a time in flesh and strength only to lose it again.

May, 1913, careful examination of stomach after Ewald and motor meals showed only evidence of impaired motility, presumably due to the old adhesions following her first two operations.

July 16, 1913, I separated the most extensive and dense adhesions I have ever seen that were uniting stomach, duodenum, liver and anterior abdominal walls, and then over all the extensive area thus denuded I anchored omentum to prevent reformation of adhesions and limitations of the stomach and duodenal functions. Slight acute dilatation threatened for a couple of days, but yielded to the use of the stomach tube, after which recovery was uneventful and the patient gained about 30 pounds in weight in three or four months, but within eight months there was a return of the old symptoms and loss of all she had gained.

CASE C.—Mrs. G., referred by Dr. J. W. Garver, Peru, Iowa, was operated on in January, 1910, for cholelithiasis; in April, 1910, ovariectomy was done; in January, 1911, she was operated on for ventral hernia, and in September, 1911, for appendicitis. She came into my hands July 25, 1912, suffering from severe attacks of pain and vomiting. Pain was vaguely located in her upper abdomen. Her strength, however, was good and she was quite obese. She had dilatation of the stomach, and nearly all the omentum she possessed had been used up in adhesions resulting from previous operations. We had decided on gastrojejunostomy as the safest and surest means of relief, but finding a gall-stone of considerable size, it was removed and drainage of the gall-bladder was done, after which I did my regular posterior gastrojejunostomy without loop, with rubber dam over the posterior edge of the anastomosis. She has for nearly two years since operation been free from pain and vomiting, and has made considerable additions to her already abundant adipose.

These cases are presented as object lessons, in the belief that an analysis of the cases in which bad results were obtained or in which the patients were relieved

only after four or five operations may help us in reaching the goal at a bound, or at most a second trial, in competent hands instead of repeatedly jeopardizing life in new operative attempts in which the surgeon's operative difficulties have been doubled or even quadrupled by previous bungling.

It is to be hoped that a better understanding of the value and use of the omentum may soon become more general among those who essay the art of surgery, that the stomach and intestines particularly may be less impaired in their subsequent functions after all abdominal work, but especially in the upper abdomen. All friction of a delicate endothelial surface in the abdomen by gauze of any kind must be avoided or reduced to the minimum. Especially must no dry gauze be allowed to ever come in contact with any endothelial surface in the abdomen unless it be for the deliberate purpose of destroying or injuring the same and causing adhesions as may be justifiable in attempts to secure omental vascular attachments to the abdominal walls in cases of ascites. The slightest contact of dry gauze with any of the endothelial lining of the abdominal cavity will destroy much of its surface.

Carelessness in failure to protect the intestines and omentum from skin contact, now that the use of iodine in skin preparation has become almost universal, is another cause of adhesion complication in otherwise clean and satisfactory operative procedures. It is not an uncommon sight in the operating room to see large masses of abdominal viscera rolled out of the abdomen on a skin surface, but recently painted with Churchill's tincture of iodine.

COMMENT ON OPERATIONS IN TWENTY-THREE CASES

The twenty-three cases in which operation was performed in the few months covered by the report present an average age of 46 $\frac{1}{6}$ years, the oldest patient being 71 and the youngest 27 years of age.

Fig. 7.—Same as Figure 6 (Case 21), showing abdomen after removal of drainage tube.

Seven of the cases are noted as in a critical condition, by which I mean that they were emergency cases as truly as the average acute appendicitis.

One patient, however, was in the last stages of pulmonary tuberculosis and was operated on because of the terrible suffering from the cholelithiasis from which she begged operative relief. She recovered without incident from the operation, but died from tuberculosis soon after her return home. The operation gave her immediate and complete relief from pain.

There was only one fatality, and that in a man aged 71, who had had biliary obstruction for four months, was in *extremis* with profound sepsis and numerous infarcts in the liver, and the gall-bladder showed necrotic points.

Ether was the anesthetic used in all but the tuberculosis case, in which chloroform was given.

The operation time ranged from thirty minutes to one and three-quarter hours, according to the severity, difficulty and number of complications handled.

Gall-stones were found and removed in fourteen cases, no stones in nine. In Case 9, however, while

Fig. 8.—Showing applicability of method in case of general suppurative peritonitis complicated by acute dilatation of stomach, with enormous amount of fecal matter in the organ. Patient apparently moribund four days before abdominal section. Although median wound was bathed in purulent matter, union of the parts was obtained without any difficulty.

we found no calculi we did find a pure streptococcus infection, and he had a leukocytosis of 62,200, with 90 per cent. of polymorphonuclears. Fifteen cases showed colon bacillus as the infecting organism, three of which had joined company with the staphylococcus, and in one case both streptococci and staphylococci were present.

Other operations and diseases are noted as complications and were present in twenty of the twenty-three cases.

Of these complications nine are appendectomies, two ventral herniotomies, two umbilical herniotomies, two perineorrhaphies, two ovariectomies for ovarian cysts, one trachylorrhaphy, three hemorrhoidectomies and one phlebitis. Three patients had profound sepsis, and in one of these gravely septic cases the gall-bladder mucosa, being necrotic, was removed. In only one case was a cholecystectomy done, and in one the mucosa of the gall-bladder was removed. All cases were drained until the discharge was nearly or quite sterile. In all but three cases the gall-bladder was inverted around the drain and all closed within one week after the drainage tubes were removed, and some did not drain longer than two days after removal of the tube.

One case was complicated by visceroptosis and in that case the ptosed condition received operative attention.

One case developed consolidation of the entire right lung on the tenth day (pneumococcal infection), and in this case the infecting organism in the gall-bladder was a pure primary streptococcus.

In the series of twenty-three cases cholecystotomy was complicated by no less than twenty-nine operative or other conditions of greater or less importance.

If this small number of cases can be said to carry any important lessons for us it would seem to be that cholecystotomy without grave complications should be practically without mortality.

Cholecystotomy is no bar to other operative procedures if the patient is in good condition and the operations be properly done with sufficient dispatch, and whenever possible other important pathologic conditions should be eliminated as far as it is consistent with safety to the patient.

ABSTRACT OF DISCUSSION

DR. FREDERICK COTTON, Boston: We all see a lot of cases in which a secondary operation in gall-bladder surgery is necessary, and we all know the difficulty of preventing adhesions. Dr. Ruth spoke particularly of the median incision, which is not the usual incision made. I think we all agree that the old incisions are unnecessary; but as between the more usual incision at the side of the rectus abdominis and the median incision, there are certain grounds for debate. I have used the median incision for a good while in explorations and used the rectus incision for gall-bladder drainage. The danger of hernia is not common unless a duodenal leak occurs. I have seen only one case after digestion of the abdominal wall for weeks from escaping pancreatic juice. Hernia is not a particularly important factor in these upper abdominal cases if good closure is obtained.

DR. EDWARD MARTIN, Philadelphia: Concerning but one or two points in Dr. Ruth's paper there may be a difference of opinion. Surgeons who operate on the liver and ducts may be compared to plumbers. A first-class plumber always leaves something to go back for. With the surgeon this something is not intentional but is incidental to an incomplete preparation and operative diagnosis. In a number of operations for gall-stones they have not been found, or, indeed, anything else which could be bettered by surgical intervention. Under such circumstances if there be no evidence of back pressure, if the gall-bladder is normal and has not been treated brutally, what particular reason is there for drainage? The gall-bladder is easily, quickly and permanently closed, and the wound convalescence is as prompt as is that from any simple incision. Dr. Ruth advocates a median incision. In certain patients with lax abdominal walls the median incision will reach any point; but why we have adhesions, why we fail to find gall-stones, or to diagnose pancreatic conditions, is because we do not provide adequate access, without visceral and parietal trauma. The vertical cut if made in women with fat, full, tense abdomens gives poor access. If made to the inner side of the middle of the rectus muscle it divides no nerve trunks. If made to the outer side it divides the nerve-supply and is followed by atrophy of the rectus segment. Hernia develops and may become a distressing complication. Moreover, a satisfactory closure of the deeper part of the parietal wound is often difficult or impossible. The incision which gives best access, is least destructive and is most readily closed is first a vertical midline cut for primary exploration; then a transverse cutting of the rectus muscle five fingers' breadth above the umbilicus, a splitting of the external oblique, cutting of the internal oblique and a splitting of the transversalis upward and outward toward the costal border. The whole flap is turned up, when the liver and its ducts are entirely accessible for exploration or operation. Under this incision I have exposed and satisfactorily drained an abscess at the very top of the liver not bigger than a small apple. How many operators have been satisfied with closure of a vertical cut in one of the fat, full abdomens, the stitches tearing through the posterior rectal sheath on the slightest tension? The view of such a wound from within the abdomen gives a picture widely differing from that suggested by the final neat skin closure. With the vertical and transverse cut, the stitches hold because the direction of their pull is across that of the

muscles and fascia, the wound comes together easily and the ultimate closure is good. Two fingers' breadth above the umbilicus is the usual position of the transverse tendinous lines of the rectus muscle. The suture is somewhat easier if the cut be carried through the line. This is, however, not necessary as mattress sutures readily approximate and hold in place the cut muscle surfaces.

DR. PHILANDER HARRIS, Paterson, N. J.: In operating on the gall-bladder for gall-stones I have employed one or other of the vertical or downward incisions. I have operated a few times by the central incision but not sufficiently often to become familiar with it. If I should adopt the central incision I question whether I could so easily deliver a portion of the liver as I can with the vertical incision. Whatever I might say against the central incision would be theoretic and not entitled to any consideration. I have employed nothing but stab-wound drainage in operating for gall-stones in more than eight years. I certainly feel that the best way to get undesirable secretion out of the body is to bring it through a stab-wound incision, getting as far to the right as has been indicated by Dr. Ruth. I do not drain through the incision, nor do I sew the gall-bladder to the peritoneum. The advantage, I believe, of stab-wound exit and efficient drainage established in that manner arises from the fact that it is on lower ground. Unless the patient is turned well to the right it is a decided advantage to have the drainage at the lower point of the incision and to the right of it. The operation might, perhaps, be improved by employing two large tubes instead of one. I have employed twin drainage with stab-wound exit for five years. With the double drainage two tubes come out of the stab-wound exit and from each of them there is a drainage pail. One tube may enter the gall-bladder; the other, any desired place. The gall-bladder is sewed with very fine catgut around the tube which enters it, and the catgut by which the fundus of the bladder adheres to this tube is carried out through the stab-wound by means of the forceps. In the first twenty-four hours blood comes out through the little triangular space. In two or three days the wick is withdrawn and the tubes may be left as long as desired. I believe that the operation of cholecystectomy is gaining ground while the operation of cholecystotomy is taking a less important place.

DR. D. N. EISENDRATH, Chicago: We are passing through the same stage with regard to common-duct surgery that we have passed through with the gall-bladder proper. There was a time when one could only make a diagnosis of gall-stones when the patient had jaundice. That we cannot have common-duct stone without jaundice is a belief that had better be dropped. I find that the secondary cases have been those in which the gall-bladder has been taken out and in which the operator did not have the courage to take out the common duct. It is time for us to decide that when we operate for gall-bladder disease we have to consider also the condition of the common, hepatic and cystic ducts. If I find gall-stones in the gall-bladder it is the last part of my operation. As Dr. Martin said, we cannot get as good exposure of the common duct through the median as through the lateral incision. Kehr, a year ago, reported 54 cases in which he had examined the common duct and in 32 palpation was negative and yet stones were found. In over 50 per cent. of my cases when palpation was negative, by opening the common duct I have found stones. My technic is to leave the gall-bladder alone at the early part of the operation, take a couple of traction sutures and open the common duct between them, explore toward the ampulla and up into the hepatic duct. A considerable number of the so-called secondary operations are due to overlooking common-duct stones. Another element of failure is leaving a gall-bladder in, which ought to have been taken out at the first operation. Taking the gall-bladder out in the secondary operation is most difficult. Everything is so adherent that you cannot get a line of cleavage. This can be avoided if the gall-bladder is taken out primarily. When the common duct is enlarged to the size of the index finger, or its walls are thickened or there are many small stones in the gall-bladder the common duct

must be explored. If there is marked pancreatitis, drainage of the common duct is also of much benefit. It has been shown experimentally that at the end of three weeks the bladder, no matter how badly infected, is sterile.

DR. J. H. CARSTENS, Detroit: It seems that all these cases depend on circumstances. We can remove the gall-stones, sew up the gall-bladder and drop it back. If there is an infected gall-bladder this cannot be done. It can be done only with the mulberry variety of gall-stones; this I often do. In clean cases I make the incision transversely in the direction of the fibers of the external oblique muscle, separating them and pulling them apart. Then I separate the fibers of the rectus in the opposite direction without cutting them and pull them apart. I separate the transversalis fibers and take hold of the gall-bladder, opening it and remove the stone or stones, and carefully close it, bringing the edges together and amplifying it with a row of Lembert sutures. I then drop the gall-bladder and close the opening in three layers. The incision is always very small. I thus have not cut any nerves and there is no danger of hernia. I make the same incision in ordinary cases, when I want to drain but do not attach the gall-bladder to the incision. In some cases there are extensive adhesions but they have produced no symptoms. I generally can feel the ducts, and if I find no trouble I let the adhesions alone, because if they are broken they may produce new adhesions that will cause serious symptoms. I separate only enough adhesions to get to the top of the gall-bladder, which I open, scoop and float out the gall-stones, and insert a drainage-tube. If I have an infected gall-bladder I do not operate until the acute inflammation has subsided, if possible. Then I make as small an incision as possible, pull up the gall-bladder and stitch it all around to the peritoneum without opening it. I have thus the peritoneum clean and closed and can open the gall-bladder and wash out the gall-stones without danger of infection. Sometimes I also take out the gall-bladder if it is gangrenous, or remove only the lining membrane. As a rule, before I touch the gall-bladder I explore the ducts. If they are pervious and contain no stones I let them alone; if they are large I split them up, but I would not split up every one when there is nothing the matter with it. In some of these cases we also have a loose liver coming down and causing great distress. In such cases I generally scrape the surface of the liver and the anterior peritoneum behind the ribs, shove the liver into place as nearly as possible and then stitch the gall-bladder to the incision, which I make quite high, and it helps materially, I think, to keep the liver in place, although the latter may become sufficiently adherent to relieve the symptoms without the attachment of the gall-bladder.

DR. JOHN A. MCGLINN, Philadelphia: I take the rather advanced stand that gall-stone disease is essentially a surgical and not a medical condition and if diagnosed the stones should be removed. I do not believe that gall-stones may be innocuous for a number of years and no pathology result from their presence or the original cause of the stones. Four years ago I studied and reported observations on the pathologic findings in 506 cases of gall-stones. In all of these cases gross pathologic lesions were found either in the biliary tract or adjacent organs. It is interesting to note that the lesions were practically always multiple. This explains why it is so often necessary to reoperate in gall-stone cases. The tendency is simply to remove the stones when found and not seek for other pathologic lesions. It should be borne in mind that the whole right upper quadrant of the abdomen should be explored in operating for gall-stone disease, so that lesions of various parts of the biliary tract as well as those of adjacent organs can be dealt with.

DR. F. D. GRAY, Jersey City, N. J.: The question of double drainage mentioned by Dr. Harris should, to my mind, only arise under exceptional circumstances. It might be considered when the field of operation has been soiled or when there is uncontrollable oozing of blood. Again there may be a doubt in one's mind whether the sutures will hold in unusually softened tissues with a resultant leakage. If

there is any necessity for drainage, except that of the gall-bladder, it appears to me that a drainage tube will, in that location not be sufficient, on account of the tendency of septic fluids to gravitate into the lower abdomen. The most effective thing under these circumstances is to introduce a strip or two of iodoform gauze beneath the gall-bladder (or its stump in cases of cholecystectomy), below which is inserted a layer of dental dam, to prevent adhesions, the whole of which constitutes a coffer dam, as it were, to intercept and carry all drainage fluids to the surface. In my opinion this is more effective than a second tube can be and I have had good results with the method.

DR. CHANNING W. BARRETT, Chicago: The necessity for the median incision can be done away with by a double incision instead of a compromise one to reach two extreme ends of the abdomen. The compromise incision never reaches either end very well. If the gall-bladder is to be operated on, a 3-inch incision will attend to that. This can be made without injury to the abdominal wall and nerves.

DR. C. E. RUTH, Des Moines, Iowa: I use the stab-wound drainage because properly used it will never produce hernia. No drainage, however, can be continued through any wound without some infection about it, and for that reason there is a liability that if we use the main wound for drainage we will add to or cause infection that could be avoided. So far as hernia is concerned, possibly it is not common in the East, but it has been with me a source of great trouble, not in my own cases, however. The secondary cases coming to me with hernia are not a few. In determining the time of drainage we have, in practically all our cases for the last year and a half, made repeated cultures before we allowed closure of the wound. We never allowed the wound to close until the primary infection had become decidedly diminished in virulence. The staphylococcus from the skin we try to avoid by taking our cultures far down in the gall-bladder. With reference to stones being the cause, as mentioned by Dr. Martin, for this operation, I believe they are the primary cause of infection. I never object to the straight median incision and I increase the size if necessary to get the space for rolling the liver out. I do object particularly to the old longitudinal incision that starts under the rectus and which, if prolonged, does cause destruction of the nerve-supply to a portion of the abdomen. If one prefers to use two incisions I have no objection, but I prefer one. I have never found it necessary to use more than one, or to curve the incision to the right. I can conceive of the possibility for it, but so far have not found it necessary. There is no question that the use of two tubes when the peritoneum is soiled, is good practice. I have abandoned stitching the gall-bladder to the peritoneum because of the traction. I like the use of the round ligament for the suspension of the gall-bladder.

TREFOIL OR STELLATE KERATECTOMY FOR ANTERIOR STAPHYLOMA *

S. LEWIS ZIEGLER, M.D.
PHILADELPHIA

Keratoplasty has been successfully employed to remedy certain corneal defects, but only a moiety of procedures have been devised to meet the indications present in anterior staphyloma. When a protruding but circumscribed corneal ectasia has proved to be more or less obstructive to the vision, and the remaining tissues of the globe have not been seriously involved in the pathologic process, conservative surgery demands that a mobile globe shall be preserved, and, whenever it is possible, that a modicum of useful vision shall be secured.

To meet these indications I devised, in 1895, a simple form of corneal excision, which I have designated as *trefoil keratectomy*. It is adapted chiefly to those cases in which a limited portion of the cornea is staphylomatous and in which correction of the ectasia can be made by the removal of a three-leaved flap from the lower part of the pendulous cornea (Fig. 1). When, however, the whole cornea is involved and a four-leaved flap must be excised to correct the deformity, the procedure is designated as *stellate keratectomy*.

PRELIMINARY TREATMENT

Full antiseptic precautions should be observed, as most cases of corneal staphyloma are the result of infectious processes, such as trachoma, suppurative conjunctivitis and other mucopurulent discharges. A course of sedative treatment should, therefore, be applied to the palpebral conjunctiva. As many of these cases are complicated by lacrimal blennorrhea or obstruction, it is often necessary to perform rapid dilatation of the tear-duct. If this is indicated, it should be done at least one week prior to the corneal excision. It is often wise to irrigate the nose with an antiseptic wash.

ANESTHESIA

This operation has been performed under cocaine-epinephrin anesthesia, but full ether narcosis is to be preferred, since the restlessness of the patient might interfere with the proper introduction of the sutures, or even cause an injury to a transparent lens, if such should be present.

Fig. 1. — Vertical section of anterior staphyloma, showing clear cornea above and ectasia below. The thickened iris-tissue has been glued to the cornea by plastic inflammation.

INSTRUMENTS REQUIRED

In my earlier operations I used a speculum, Graefe knife, fixation forceps, a pair of small, strong scissors, a needle-holder, needles and fine black silk sutures. In cases of emergency an iris forceps, iris scissors, silver spoon and spatula, and a wire loop may be required and should be included on the tray. In a later method I changed the technic by substituting a keratome for the Graefe knife, and a corneal punch (Fig. 2) instead of the scissors. The two methods appear to be equally efficient, although in certain cases the punch cannot be used because of lack of space in which to introduce it.

DESCRIPTION OF OPERATION

Three methods will be described, (a) trefoil keratectomy with the scissors, (b) trefoil keratectomy with the punch and (c) stellate keratectomy with both scissors and punch.

Trefoil Keratectomy

Scissors Method.—First Stage: With the speculum inserted and the globe firmly held by fixation forceps, the operator should first inspect and outline the exact area to be excised (Fig. 3A). The Graefe knife is then passed horizontally through the base of the staphyloma from the temporal to the nasal side, keeping the edge of the blade turned directly forward, as for a Saemisch incision, and drawing it backward and forward but not allowing it to emerge fully until the aqueous fluid has completely escaped (Fig. 3B).

* Read before the Section on Ophthalmology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

Second Stage: One blade of the scissors is now introduced beneath the upper margin of the horizontal incision, a little to the right of the center (2 or 3 mm.), and a long vertical incision made. A second converging cut is then made, the same distance to the left of the center, which joins the first at the apex and thus makes a V-shaped incision and opening (Fig. 3 C).

Third Stage: The two corners of the opposing wound-margins are successively grasped with the forceps and a triangular piece (Fig. 3 C, upper margins) excised by scissors from each corner, thus making a three-leaved opening (Fig. 3 D).

Fourth Stage: The vertical wound is closed by two or three fine black silk sutures passed through the opposing wound-margins and tied (Fig. 3 E). The horizontal wound is then sutured in like manner (Fig. 3 F).

A Kalt suture (linen) may, if preferred, be inserted through the outer layers of the cornea and tied as a mattress-suture. The cut surfaces must be carefully approximated at all points.

Punch Method.—First Stage: A vertical incision is made through the base of the staphyloma with an angular keratome (Fig. 3 G), and the inferior blade of the punch is passed into the anterior chamber and beneath the cornea, while the punch is closed with a

Fig. 2.—Corneal punch, with long oval points. The spring was adapted from McClure's iris scissors.

short, quick thrust, thus excising the left lateral flap (Fig. 3 G, shaded part).

Second Stage: The punch is removed, introduced on the other side of the wound-edge, and the right lateral flap is excised in the same way (Fig. 3 H, shaded part).

Third Stage: The upper margin of this long, oval wound is now grasped at its center by the punch and a vertical piece excised (Fig. 3 I, shaded part), leaving a trefoil opening (Fig. 3 D).

Fourth Stage: The sutures are now inserted to close first the vertical wound (Fig. 3 E) and then the horizontal wound (Fig. 3 F), as previously described.

Stellate Keratectomy

This operation is chiefly indicated when the staphyloma involves the whole of the cornea, or when a central mushroom staphyloma has developed. It can be performed either with the knife and scissors or with the keratome and punch, as is preferred.

First Stage: A horizontal incision is made in the center of the cornea, with the Graefe knife or with the keratome (Fig. 3 J).

Second Stage: The upper and lower vertical flaps are excised with the scissors or with the punch (Fig. 3 J).

Third Stage: In like manner the two horizontal flaps are excised (Fig. 3 K).

Fourth Stage: Each section of the stellate¹ incision is closed by a single suture, and a central mattress-suture is finally inserted.

COMPLICATIONS

If, by chance, abnormally high tension should cause extrusion of the lens, or if vision can be improved by the removal of a cataractous lens, the loop or the silver spoon should be used for this purpose and the toilet of the wound made before tying the sutures. If it seems possible to improve the vision by iridectomy or by De Wecker's iridectomy, this may be done before the wound is closed, but *pari passu*, it is better to postpone such an attempt until after healing has occurred.

Fig. 3.—Incisions and sutures for both trefoil and stellate keratectomy; A, three-leaved flaps outlined; B, corneal incision below, à la Saemisch, shaded part of upper flap ready for removal; C, upper flap excised, left tip shaded; D, trefoil keratectomy completed; E, vertical wound sutured; F, both vertical and horizontal wounds sutured; G, vertical keratome incision for punch operation, left flap shaded; H, vertical keratome incision for punch operation, right flap shaded; I, right and left flaps excised, upper flap shaded; J, horizontal keratome incision for stellate keratectomy, upper flap excised, lower one shaded; K, upper, lower and left flaps excised, right flap shaded for removal; L, stellate keratectomy completed and sutures inserted.

POSTOPERATIVE TREATMENT

Mercuric chlorid ointment should be inserted into the conjunctival culdesac and a light bandage with a cresol solution compress adjusted. A slow-healing wound may be stimulated by touching it with a weak solution of silver nitrate. An infected wound should have an application of liquor formaldehydi, 0.5 per cent., and ice-pads should be applied. A wound that

1. Since preparing this paper my attention has been called to the star-shaped incision of Attias, recently devised and published in the *Ophthalmoscope*, January, 1914. His sutures cross over from the upper right flap to the lower left flap and vice versa.

slightly gapes or shows other irregularity should receive a gentle touch with the hot galvanocautery point.

REPORT OF CASES

I shall briefly cite three interesting examples of this keratoplastic procedure in types that are quite diverse, the first occurring in an extremely attenuated cornea that had yielded to a superficial necrosis through the erosive action of a blennorrhea, the second in a cornea that was practically normal except in the ectatic area involved, and the third in a cornea that was greatly thickened by plastic deposit and made staphylomatous by the increased intra-ocular tension behind it.

CASE 1.—Margaret M., aged 19, was first seen by me during an attack of typhoid fever, March 17, 1895, in consultation with Dr. George Morley Marshall, the present otologist at St. Joseph's Hospital, who was at that time in charge of the medical service. There was primary infection of the ethmoid and antrum, with secondary involvement of the ears and eyes, the former through an infectious otitis media purulenta and the latter through a profuse blennorrhea of the lacrimal sac, which kept both eyes bathed in a purulent discharge in spite of free irrigation and ice-padding. The left eye showed multiple areas of corneal ulceration with some ectasia. The cornea of the right eye was markedly involved by sloughing keratitis. One week later it was found necessary to perform a Saemisch incision in the right eye to check the corneal slough, but the globe proceeded to shrink and was finally enucleated, June 10, 1895, at which time rapid dilatation of both tear-ducts was performed, *ad maximum*.

Oct. 28, 1895, an examination of the left eye showed adherent leukoma with marked anterior staphyloma, the ectasia being very thin and bulging forward below, as illustrated in Figure 1, while a small area of clear cornea was still preserved along the upper margin. The eyelids could not be closed over the staphyloma. The vision was limited to light perception and light projection. There was no discharge present.

Fig. 4 (Case 2).—Result of keratectomy in the right eye; clear cornea above; flat leukoma below; final vision 20/100.

As the patient had been able to count fingers before the pupil was drawn into the scar, and as the globe seemed to be healthy, I decided to make a plastic operation on the cornea. Ether was administered and trefoil keratectomy was performed, the primary incision being made with a Graefe knife through the base of the staphyloma, after which a large vertical flap was cut out with the scissors and the two lateral tips later excised. The iris was freed from above. The corneal wound was closed by fine black silk sutures, the vertical first, and the horizontal last. Healing was uneventful and the cornea became nicely flattened. Vision had recovered to the degree of 10/200 at the time of patient's discharge from the hospital.

CASE 2.—Mary McC., aged 19, applied to Wills Eye Hospital March 20, 1908, suffering from corneal staphyloma of the right eye, down and in. Scar was somewhat weakened at lower margin. Cornea was clear above. The globe was not involved. Tension +1. Iris was adherent to the scar. The lesion was the result of a blow received during childhood. Iridectomy was performed by me four years ago.

April 24, 1908, patient was admitted to the hospital during the internship of Dr. J. Milton Griscom, at present assistant surgeon to the hospital, to whom I am indebted for these notes. Trefoil keratectomy was performed and the wound sutured.

May 1, 1908, sutures were removed.

Fig. 5 (Case 3).—Large leathery staphyloma excised in the right eye, leaving a well-flattened cornea.

May 3, 1908, shallow anterior chamber, due to a small break in the line of the wound.

May 5, 1908, deep anterior chamber. Wound closed.

May 20, 1908, patient was discharged cured. Cornea was firm and flattened. Vision 20/100. The present appearance of the right eye is well shown in Figure 4.

CASE 3.—Alphonso R., miner, aged 47, came to Wills Eye Hospital, Dec. 4, 1908, with ulcerative keratitis and adherent leukoma, the result of severe traumatism from a flying piece of steel, six weeks before. Perforating ulcer, 3 by 4 mm.

Dec. 6, 1908, Stilling's operation with lead style and rapid dilatation of tear-duct was performed to eliminate the danger of lacrimal infection.

Jan. 13, 1909, iridectomy was made for visual purposes.

Jan. 29, 1909, patient was discharged without visual improvement.

July 12, 1909, patient returned with large staphyloma of cornea at the site of the old scar. Marked interstitial thickening of the cornea, which resembled leather in looks and feeling. Tension was +2. Under ether anesthesia three triangular areas were excised with the corneal punch (trefoil keratectomy) and the necessary sutures inserted. The sudden release of intra-ocular pressure caused the lens to be extruded, but no other complication ensued.

Aug. 20, 1909: Recovery was uneventful. Patient was discharged with a well-flattened scar but no improvement in vision. Figure 5 shows the appearance of the eye at that time.

1625 Walnut Street.

ABSTRACT OF DISCUSSION

DR. JOHN GREEN, JR., St. Louis: The surgery of corneal staphyloma dates from the Alexandrian period of Greek and Roman civilization. It is not surprising that these beauty-loving peoples should have devised methods to diminish a deformity which, in its higher degrees, is irksome to the victim and repulsive to those with whom he comes in contact. The method adopted was that of ligation: A needle bearing a doubled thread was passed through the base of the staphyloma; the needle then was cut off, and the tumor tightly enclosed within the bight of the thread above and

below. The method was modified by passing needles similarly armed, at right angles, then tying off the tumor in four sections. Beer, in 1805, proposed and practiced simple abscission, without suturing the gaping wound. Critchett, 1863, in order to retain a part of the vitreous, passed curved needles through the sclera and ciliary body, entering above and emerging below the staphyloma, which was then abscised. Knapp, 1868, modified the method by quilting his sutures horizontally through the conjunctiva and episclera. DeWecker, 1873, circumcised the conjunctiva at the base of the staphyloma, abscised the protruding mass and drew the conjunctiva together with a purse-string suture. The outcome of these various operations is often very satisfactory: a globular mass of varying size, freely movable by reason of undisturbed muscular attachments. The artificial eye is often remarkably life-like, fully as prominent as its fellow and with really extraordinary lateral and vertical mobility.

It has been contended, and with some justice, that in the case of laborers, a blind eye, even though unsightly, that is painless and free from congestion, is better for the individual than the best prosthesis. If then, a protruding staphylomatous mass can be flattened by operation, and the result be a quiet blind eye, only disfigured by a flat scar, it is pertinent to inquire whether such a procedure may not only be justifiable but also definitely indicated. For partial staphyloma Dr. Ziegler's trefoil keratectomy appeals to me as an excellent measure. It seems possible that the technic might be simplified by omitting the approximating sutures and covering the cornea with a double pedunculated conjunctival flap. Possibly a double overlying flap, drawn from either side of the cornea (similar to Francis' double flap for scleral wounds) might serve still better. More and more ophthalmic surgeons are using these flaps to great advantage in both linear and jagged wounds of the cornea, and I see no reason why such a flap should not be serviceable in the condition under discussion. The indications for stellate keratectomy for total staphyloma in a blind eye seem to me far less clear. I should feel that an eye so operated on was somewhat of a menace to its fellow. I should prefer either to leave it alone or to enucleate, with a fat, glass or gold ball implantation in Tenon's capsule.

DR. JOHN E. VIRDEN, New York: I have had no experience with Dr. Ziegler's operation, but in connection with partial staphyloma I have had recently two or three pleasing experiences without surgery in cases of early staphyloma of the cornea, in which I followed a suggestion I read, by some foreign authority; that is, the dropping into the eye three times a day of a 1:1,000 epinephrin solution, which reduces the tension and allows nature to fill up the gap. I have had two very beautiful recoveries from that procedure.

DR. S. LEWIS ZIEGLER, Philadelphia: With reference to the use of epinephrin in the treatment of staphyloma, this suggestion was made by my colleague on the staff of Wills Hospital, Dr. Paul J. Pontius, who published a series of cases in the *New York Medical Journal*, Sept. 28, 1912. It is a most excellent procedure, but the preparation must be used in full strength (1:1,000) and instilled 3 times a day. It is chiefly applicable to cases of partial or total slough of the cornea, where suppuration has ceased and ectasia is just beginning to manifest itself. Under this treatment the regenerative process will so stiffen the cornea as to prevent the formation of staphyloma. It has proved very successful in my hands. The conditions that I referred to in my paper were not the conditions that Dr. Green mentioned in the first part of his discussion. I was not referring to staphyloma that involved more than the corneal tissue and did not intend to include staphyloma that extended into the ciliary region. The suggestion of covering the wound with conjunctiva I think is an excellent one, if the technic of Kuhnt is followed. On the other hand, there are many cases in which the cornea is so stiffened by reduplication of tissue and formation of plastic deposit that the wound when it is incised does not coaptate and you must draw it together with a suture. The sutures can be put in by my method, by Kalt's or by any of the others. I do not think that we have anything to fear from the use of sutures in this character of tissue, or in other types of leukomatous cornea. They have been used very freely and

successfully. I have nothing further to add to the operation except to say that I feel sure those who will try it in the cases indicated will find it a successful procedure, without danger of complications and with great benefit and satisfaction to both patient and surgeon.

IMMUNITY IN MEASLES

CHARLES S. WOODS, M.D., IOWA CITY, IOWA

Hektoen¹ concluded from his study of experimental measles that "the virus of measles is present in the blood of patients with typical measles some time at least during the first thirty hours of the eruption."

It would seem that Hektoen's experiments prove beyond a doubt that measles may be transmitted by injecting the blood of a person having measles into another person in normal health. One would expect, therefore, that infants *in utero* would be liable to contract measles if the mother should happen to have the disease during pregnancy. I wish, therefore, briefly to relate an observation which I have had the opportunity of making on this point. About seven years ago I called to see a woman who presented the usual signs of measles. She had never had the disease. Two children in the family were just recovering from it. She was in the eighth month of pregnancy. I was greatly concerned and hourly expected a premature birth of the child. The attack of measles was quite typical. The patient was very uncomfortable, chiefly because of the bronchial involvement. She passed through the attack without any unfavorable results. About three weeks later I delivered her of a normal child.

I supposed that the child had acquired the disease from the mother, and perhaps he did. Only recently, however, I have received word from the father that the child had a rather severe attack of measles this spring. And while it is true that measles may attack a person a second, and even a third time, this child while *in utero* must have had the most ideal opportunity for acquiring immunity against this disease. It is generally believed that if a pregnant woman is infected with syphilis late in pregnancy the child usually escapes.

It is impossible to say that this child did not have measles *in utero*. Children have been born with measles, small-pox and certain other diseases which were certainly contracted from the mother.

This case emphasizes the very great difficulty in securing immunity, as well as the remarkable power of the virus of measles to invade the human organism.

RETROPERITONEAL HERNIA DUE TO AN ABERRANT MIDDLE COLIC ARTERY*

A. PRIMROSE, M.B., C.M. (EDIN.), M.R.C.S. (ENG.)

Associate Professor of Clinical Surgery, University of Toronto, Faculty of Medicine; Surgeon, Toronto General Hospital

TORONTO

Retroperitoneal hernia is not a common condition, but it occurs with sufficient frequency to warrant a very careful study of its cause, the symptoms it may produce and its treatment. A critical analysis of the whole subject will be found in the monograph written by Sir Berkeley Moynihan entitled "On Retroperitoneal Hernia," a second edition of which was written

* Read before the Section on Surgery, General and Abdominal, at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.
1. Hektoen: Experimental Measles, *Jour. Infect. Dis.*, 1905, ii, 233.

in collaboration with Mr. J. F. Dobson in 1906. This work contains a very complete bibliography, and the author has narrated in detail many of the cases which have been recorded in the literature. The etiologic factor responsible for the production of this class of hernia has, in the vast majority of instances, been demonstrated to exist in the numerous peritoneal folds and fossae which are produced in the normal development of the intestinal tract and its serous covering. These folds and fossae are formed mainly in four distinct regions. They are as follows:

1. Duodenal folds and fossae in the region of the duodenojejunal juncture. Here we have, in addition to a few extremely rare types, the two chief varieties of (a) "left duodenal hernia," and (b) "right duodenal hernia."

2. Peritoneal folds and pouches in the region of the cecum and vermiform appendix. These are responsible for a considerable variety of cases of "pericecal hernia."

3. The fossa at the base of the mesentery of the sigmoid flexure of the colon. Hernia into this fossa has been described from time to time.

4. The region of the "lesser sac" of peritoneum and the foramen of Winslow. Hernia occurs into the lesser sac of peritoneum through the foramen of Winslow, or again there may be hernia into the lesser sac through an abnormal aperture, as through the lesser omentum, the gastrocolic omentum, the great omentum or the transverse mesocolon.

Among the earlier writers on this subject we have Treitz, Waldeyer, Eppinger, Toldt and Jonnesco. The Hunterian lectures of Treves in 1885 on the anatomy of the intestinal canal and peritoneum in man make a well-known monograph containing a study of the peritoneal fossae. Again Huntington in his exhaustive and beautifully illustrated work on "The Anatomy of the Human Peritoneum and Abdominal Cavity Considered from the Standpoint of Development and Comparative Anatomy" (1903) gives us an account of the various fossae concerned in these forms of internal hernia. The writings of Lockwood and Rolleston and of Berry on this subject may also be referred to.

The frequency of retroperitoneal hernia may be judged from the fact that Moynihan was able to collect from the literature 68 cases of left duodenal hernia, 17 cases of right duodenal hernia, 19 cases of pericecal hernia, 2 cases of intersigmoid hernia and 12 cases of hernia into the foramen of Winslow.

The case recorded in this paper is possibly unique, occurring as it does in connection with an extremely rare abnormality, namely, the existence of an aberrant origin and course of the middle colic artery. In this instance the artery in question arose from the right common iliac artery and proceeded upward to its destination in the transverse colon. In relation to this aberrant vessel a peritoneal pouch was developed which contained the whole of the small intestine. The case is of further interest because, while apparently all cases hitherto recorded were either found accidentally post mortem, or at operation performed for symptoms caused by the hernia (frequently strangulation), in the present instance an operation was undertaken for digestive disturbance due to an hour-glass stomach, and the retroperitoneal hernia found on opening the abdomen was not accountable for any symptom whatever save a slight degree of ileostasis which appeared in the Roentgen-ray findings.

The history of the case is as follows:

J. H., man, aged 60, complained of epigastric pain for three years. As a rule the pain came on some hours after eating, but in this respect the history was somewhat vague. Eighteen months prior to operation he had a severe attack of hemorrhage, vomiting a large quantity of blood, and for several days subsequently blood was passed in the stools. This was the only time at which he suffered from hemorrhage. He had lost weight and there was an excess of free hydrochloric acid in the gastric analysis. There was a tumor situated immediately above and to the left of the umbilicus which, on examination, seemed to be incorporated in the left rectus muscle. The tumor was oval, its long axis being vertical. It was about the size of a large lemon. Roentgenograms after a bismuth meal showed an hour-glass contraction of the stomach with a marked permanent incisura toward the cardiac end. A condition of ileostasis was also noted.

A diagnosis was made of gastric ulcer with cicatricial contraction producing an hour-glass stomach. It was also

Fig. 1.—Retroperitoneal hernia due to an aberrant middle colic artery. The artist has represented the sac as if it were transparent in order to indicate its relations as described in the text.

suggested that a chronic infection of the abdominal parietes had extended from the ulcer, following in all probability a slow perforation with adhesions.

The abdomen was opened, the stomach was found adherent to the parietes and the left rectus muscle for about 4 inches of its extent converted into dense cicatricial tissue which cut almost like cartilage. In the attempt to separate the stomach the cavity of that viscus was opened. A clamp was laid flat on the anterior surface and closed so that the adherent portion of the stomach was isolated and further leakage prevented. The stomach was separated from the parietes by removing a slice of the cicatricial tissue of the parietes along with it. A partial gastrectomy was performed between Payr's gastrectomy clamps, and the affected portion of the stomach removed. Immediate anastomosis of the remaining parts of the stomach was now done and the abdominal parietes closed.

This patient exhibited a remarkable condition of internal hernia in which the entire small intestine was contained in the hernial sac. When the abdomen was first opened no small intestine was visible, but one found a large flabby sac

occupying a position chiefly in the left lumbar region and extending deep down into the pelvis. The opening of the sac lay immediately to the right of the middle line and was bounded anteriorly on its free margin by a structure which extended from the brim of the pelvis upward towards the transverse colon. On picking up this structure, which felt like a thick cord, one was surprised to find that it pulsated and thus it became obvious that a large artery formed the margin of the opening. By pinching the vessel at two points separated from one another by about an inch, it was quite easy to determine by compression the direction

Fig. 2.—Retroperitoneal hernia due to an aberrant middle colic artery (indicated by the arrow). Diagrammatic representation of a transverse section illustrating the relations of the folds of the peritoneum forming the sac.

of the blood-flow within the vessel. Pinching at a lower point obliterated the pulse above, while pinching it above had no effect on the pulsation below. It was quite obvious that the current was from below upward, and on further examination we determined that the artery arose from the right common iliac. On examination it also became quite obvious that the artery was distributed to the transverse colon and in fact was an aberrant middle colic artery.

On examination of the peritoneal sac one found that, with the exception of about 2 inches of the lower end of the ileum which passed out to join the cecum, the entire small intestine was contained within the peritoneal sac. The patient was apparently not suffering any inconvenience from the conditions which one found, and in the belief that in all probability this man, who was now 60 years of age, had had this hernia without inconvenience for the greater part of his life, and further because of the fact that it seemed almost impossible to obliterate the sac efficiently had one thought it necessary to do so, it was determined to leave matters as they were.

The patient made an excellent recovery from his stomach trouble and has remained perfectly well since the operation, which took place about six months ago.

The diagrams which I here reproduce (Figs. 1, 2 and 3) illustrate the position of the hernia and its relations.

The opening of the sac was quite large so that the fingers of one's hand could be thrust within it without difficulty. The intestine was quite readily pulled out of it and there was no constriction placed on the bowel—in fact, it seemed hardly possible for strangulation to occur. The fundus of the sac was quite free so that one could lift it up out of the pelvis, and it seemed as if one could almost shake the intestine out of its acquired bag. The descending colon lay behind the sac, the transverse colon above it and the ascending colon immediately to the right of its neck. The fixed point of the duodenojejunal junction was entirely within the sac, lying under shelter of its upper portion, and the only piece of small bowel passing through the mouth of the sac was the ter-

minal 2 inches of the ileum where it passed to the ileocecal juncture.

It would appear that the vast majority of cases of retroperitoneal hernia have a very intimate relation to the course of some particular blood-vessel; in course of development the blood-vessels lie in a retroperitoneal position, and as they course to or from the various viscera, which they supply with blood, they maintain their position in the same plane of tissue, passing between the two leaves of the mesentery in reaching the small bowel or running behind the posterior parietal peritoneum to reach such viscera as the ascending colon, which as a rule possesses no mesentery.

In the early embryo of the sixth week the intestinal canal runs a straight course and the blood-vessels are distributed to its various portions as branches of the aorta which proceed to their destination between two folds (right and left) of peritoneum, described as its mesentery. Subsequently this simple arrangement becomes complicated by rotation of the intestine and by the fusion of different layers of peritoneum. The result of these processes is to produce various folds of peritoneum and certain fossae related to these folds. These fossae normally persist in such localities as the duodenojejunal juncture, the ileocecal region, or at the root of the mesentery of the sigmoid. The free margin of the gastrohepatic omentum bounding the foramen of Winslow has a similar origin. In these

Fig. 3.—Retroperitoneal hernia due to an aberrant middle colic artery. A diagrammatic representation of a sagittal section illustrating the relations of the folds of peritoneum forming the sac.

regions therefore and in relation to these fossae, hernias are prone to develop, and the fossae are deepened as the pressure of loops of bowel is brought to bear on them until eventually large sacs may be formed, accommodating, it may be, many feet of bowel.

The fold bounding the neck of the fossa on its anterior or ventral aspect is usually occupied by a blood-vessel, and unquestionably the vessel is respon-

sible in these instances for the production of the fold and the fossa behind it. Hence in the neck of the sac in a retroperitoneal hernia we usually find a blood-vessel which forms its anterior boundary. Thus in "left duodenal hernia" the vessel found on the ventral margin of the orifice of the sac is the inferior mesenteric vein to which is, as a rule, closely applied the left colic artery, forming the so-called vascular arch of Treitz. In right duodenal hernia the vessel concerned is the superior mesenteric artery. In pericecal hernia it is the ileocolic or ileo-appendicular artery which lies in the fold bounding the fossa. The sigmoid vessels are similarly related to the neck of the sac in "intersigmoid hernia," and one finds the hepatic artery and portal vein with the bile-duct bounding the foramen of Winslow on its anterior aspect.

We may assume that the aberrant middle colic artery in my case produced a peritoneal fold as it coursed from its origin from the right common iliac artery to its destination in the transverse colon. A fossa occurring in a position posterior to the fold would permit of the formation of a hernia. Hence in this instance the neck of the sac on its anterior aspect contained in its free margin the middle colic artery.

It is a point of great practical importance to note the fact regarding the relationship of large and important blood-vessels to the neck of the sac; otherwise, in cases of strangulation particularly, one might inadvertently sever the vessel in relieving constriction and thus jeopardize the vitality of a large amount of bowel.

The anomalous origin of a "middle mesenteric artery arising from the common iliac and supplying vessels to the transverse and descending colon" has been described by Hyrtl. I have been unable to consult his original paper but a reference to this fact will be found in Quain's "Anatomy," Volume II, Part 2, published in 1899.

Moynihan describes various methods which have been adopted in individual instances to relieve constriction in strangulated hernias of this type so as to deal with it efficiently and yet to preserve the important vessels concerned, without injury. Thus the sac has been opened at a point distant from its orifice. Distended loops of bowel have been punctured and emptied of their contents in order that reduction of the size of the bowel may be accomplished. The intestine is then dislodged from the sac through its orifice. Subsequently obliteration of the sac near its orifice is brought about by sutures introduced in such fashion as to prevent interference with the circulation of blood through the vessel. In one instance the inferior mesenteric vein at the margin of the orifice was cut across but it was found to be thrombosed—presumably collateral circulation had already been sufficiently established to prevent gangrene of the bowel, as the patient recovered.

100 College Street.

ABSTRACT OF DISCUSSION

DR. CHARLES A. POWERS, Denver: The rare condition which Dr. Primrose has described is unique, and I doubt whether we will ever see a similar case. Dr. Primrose wisely permitted this small intestine occupying the very large sac to remain where it had been lodged for several years. It was doing no harm and the patient made a good recovery. A man of lesser experience and less wise judgment might have

attempted a radical cure of this hernia and thereby had a fatal result. The situation found was an unexpected one and emphasizes the fact that when we find conditions of this nature which have existed for a long time within the abdomen and which will probably do no harm, it is our duty to let them alone.

DR. WILLIAM B. COLEY, New York: I have had no experience with the particular type of intra-abdominal hernia described by Dr. Primrose. He has, however, referred to two cases of intersigmoid hernia reported prior to 1906. I believe my own case, published in the *Annals of Surgery*, July, 1909, is the only one observed in this country. Furthermore, I think my case remains unique from the fact that the hernia occurred in an infant 3 days old. The only symptoms were apparent pain (judging from the almost constant crying of the infant) and gradually increasing distention of the abdomen. When the diagnosis of intestinal obstruction was made, the condition of the child was too desperate to permit of operation. He died shortly afterward. I performed a necropsy, and found practically all of the small intestine in a retroperitoneal pouch in the intersigmoid fossa. An additional point of interest in my case was the fact that the intestine had ruptured and the whole abdomen was filled with its contents.

DR. E. WYLLYS ANDREWS, Chicago: The most valuable contribution we have in Dr. Primrose's paper is probably the one referred to by Dr. Powers, namely, the impossibility of radical operative procedure in many of these cases. What was not perhaps quite so forcibly emphasized as it might have been is the anatomic fact that every one of these retroperitoneal hernias is a constriction band formed by a blood-vessel. In the foramen of Winslow is the gastrohepatic omentum which contains the hepatic artery. It goes without saying that we dare not interfere with these structures in endeavoring to reduce. We have a left colic and the right colic form, and in all these cases constricting bands seemingly in the blood-vessels, the accidental injury or obstruction of which in relieving the band would cause a gangrene of a segment of the large or small intestine. So not only is it proved that it is the part of wisdom to let these alone when they are not causing obstruction, but it is equally true that it is impossible to relieve the obstruction sometimes when the hernial content is strangulated. We can only make some form of stoma. I refer to this in more detail in the Hernia Section of the American System of Surgery. Ample experience shows that a strangulated hernia, for example, through the foramen of Winslow, cannot be removed. The problem is then of saving life, and that can only be brought about by some method of anastomosis, external or internal. It may become the part of wisdom not to try to reduce the bowel, but to relieve its constriction and distention by some kind of a stoma or anastomosis, or by resection of the gangrene. This is further complicated in diagnosis by the fact that practically none of these cases has ever been diagnosed before operating. They are not hernias which are known and operated on as hernia. They come to us as cases of intestinal obstruction, for which we do an emergency operation. Therefore, in some respects, it seems as if they hardly deserved classification as hernia at all.

The Importance of Observation in Diagnosis.—Which is the worst error, to fail to observe certain conditions, or to observe them and interpret them incorrectly? In the writer's opinion, the first is much the worse error. Observation is a matter of patience, training and thoroughness, in all of which a man may improve himself, but the use which he makes of his observations is partly a matter of his mental equipment. True, he can train his powers of thought and judgment to some extent, but we vary greatly in the quality of our cerebral cells, and the saying of the father of medicine, "Experience is fallacious and judgment difficult," is always true. To observe correctly and decide wrongly is sure to happen to the best of us, but to observe carelessly happens only when we permit it.—Thomas McCrae, *Canadian Med. Assn. Jour.*

FURTHER OBSERVATIONS ON THE
HEMIOPIC PUPILLARY REACTION
OBTAINED WITH A NEW CLIN-
ICAL INSTRUMENT*

CLIFFORD B. WALKER, A.M., M.D.
Fellow in Ophthalmology, Harvard Medical School
BOSTON

The need of such a test as the hemiopic pupillary reaction, if it holds in cerebral cases any of the topical diagnostic possibilities originally suggested by Hed-
daeus and later elaborated by Wernicke,¹ is so great that no labor should be spared fully to estimate the value of every promise it may offer.

In a paper² before this Section last year a complete historical summary and bibliography were given of this subject and of the Wilbrand test.³

PREVIOUS OBSERVATIONS

It will suffice here to recall some cardinal points from the researches of previous observers. Most important was the work of Hess in clearly showing what a great stumbling-block the phenomenon of dispersion light within the eye media had been in both

on the retina and decreases farther away from the image, but is still strong enough at right angles to the axis of the ray to render the path of the ray visible, if observed in a dark room through a trephined scleral window in the freshly enucleated eye. A somewhat similar phenomenon is commonly observed when a searchlight is seen playing about in different directions on a dark night or when a beam of light passes through water, especially if any tur-

making and interpreting observations, and, since it has been frequently noticed in discussion that this phenomenon is still apparently a hazy concept to many, it may be worth while to dwell on it for a moment. By dispersion light is understood that light which in traveling the media of the eye is diverted by diffraction, refraction, etc., in all directions from the rectilinear path of the ray entering the eye. Dispersion light is strongest immediately about the image

idity is present. Dispersion light may also be observed in one's own eye entopically when a beam of light is so arranged as to fall entirely on one's blind spot.

Hess, in one of his crucial experiments, placed a small light on a perimeter-like apparatus so that the light could be moved off or on the blind spot. The consensual pupillary reaction was noted by means of an entopic pupillometer on the other eye. He noted

² On account of lack of space this paper has been abbreviated for THE JOURNAL. It will appear in full in the Transactions of the Section and in the author's reprints.

1. In the Wernicke reaction, as the phenomena was later commonly designated, a slender beam of light was thrown on the blind and then on the seeing retina of a hemianopic eye. Briefly, if there was no difference in pupillary reaction the lesion was central or posterior to the corpora quadrigemina and the reflex arc. While if there was a difference in reaction, the lesion was anterior or peripheral, interrupting the reflex arc from the blind retina to the sphincter iris.

2. Walker, C. B.: Topical Diagnostic Value of the Hemiopic Pupillary Reaction and the Wilbrand Hemianopic Prism Phenomenon, with a New Method of Performing the Latter, THE JOURNAL A. M. A., Sept. 27, 1913, p. 1152.

3. The results of further investigation of the latter subject are too space consuming to be included in this report, but will be given later.

no pupillary reaction when the light was moved concentrically with the fixation point above or below the blind spot onto the seeing retina; indeed, sometimes there was a slight reaction in moving from retina onto blind spot due to reflection from the bright optic disk. If, however, the light was moved slightly toward the fixation point, a marked reaction resulted. Therefore he concluded that a small area about the macula contained all the pupillomotor fibers, so that when a ray of light was thrown on the peripheral retina, the resulting pupillary reaction was due to dispersion light stimulating the macula rather than to direct stimulation of the peripheral retina. Further, he showed that the exact center of the macula was the most sensitive point in the macular region. From a study of these facts it was at once obvious that previous observations were not at all well controlled with respect to dispersion light, the properties of which really constituted the crux of the whole situation.

This fact having been established, the next step was the production of a satisfactory instrument which would perform the test and at the same time control the dispersion light. The latter could not be dispensed with but could be made to affect the macula with constant strength in one of two ways: first, by rotating a light at fixed radius from the fixation point from blind to seeing field, and, secondly, in a "hemikinetic" manner, to use the term of Hess. This involves two equal areas of light, symmetrically disposed about the fixation point, and so arranged that each area may be exposed alternately as the other is closed. The intensity of the areas of light must be controllable about the point of photometric balance, and during the period of change the total area exposed must be constant and equal in amount to the full area of one of the lights. In this way the direction of the light entering the eye may be changed, but the amount of dispersion light reaching the macula remains constant.

Hess devised an instrument of sliding shutter type to accomplish this. Two equal vertical openings of rectangular shape equidistant from the fixation point were illuminated from behind through milk glass. The openings in the sliding shutter which exposed the two areas alternately were so placed that the moment one area began to be cut off the other area was exposed by the same amount. This fulfilled all the conditions except that of symmetry during the period of change, when light is cut off from one side of one area but added to the opposite side of the other area, as is of necessity the case with all plain sliding shutters. The result of this arrangement may be a pupillary jump during the change, since at that instant more dispersion light reaches the macula from one light by addition than is subtracted from the other light. This is most obvious in the mid-position when the two half areas are found to be asymmetrically disposed with respect to the fixation point by exactly one-half the width of either area. Sliding shutters which will be light-tight have a tendency to stick at times and the resulting movement of the whole instrument is then such as to produce an oscillating series of asymmetrical positions. Further to minimize these objections, the areas have to be made as narrow as possible so that a pupillometer must be used to make observations satisfactorily, on account of the low intensity of direct illumination.

In order to obviate the difficulties of symmetry, the rotary shutter described in my last communication was devised and two or three hemiopic reactions were observed with it, but while it solved the problem of symmetry well enough, it was small, crudely made and poorly lighted as compared with the present instrument, so that a pupillometer was necessary to make observations in most cases.

DIFFICULTIES WITH RECENT METHODS

This last point brings up a consideration of some of the difficulties encountered in making observations with the various forms of pupillometers. Questions of pupillary illumination or of observation ability on the part of the patient form a basis for most of these difficulties.

Thus in the entopic pupillometer the patient observes his own consensual pupillary reaction. A dispersion circle limited in size by the pupillary margins is projected on the retina by an encapsulated point source of light fixed close to the eye and with all extraneous light excluded. Any change in the size of the pupil is noticed as an enlargement or contraction of the retinal dispersion circle which is projected into space as a sort of moon or round window of light surrounded by darkness. While the patient notices this phenomenon and reports on it he must also keep his other eye carefully on the point of fixation and pay no attention to the shifting lights in the field of vision. If a field defect is present in both eyes the entire dispersion circle will not be seen except by special arrangement, such, for instance, as was used on the instrument presented last year.

While this method is the most sensitive we have, it has the common error of all monocular pupillometers of damping, as it were, pupillary dilatations, since as dilatation comes on more light is admitted to the eye, producing a tendency to contraction. Conversely, when pupillary contraction comes on, it is exaggerated, more light being excluded. But still more confusing is the peculiar pupillary bounce present at all times with most patients, and probably augmented by the preceding factors together with psychic or perhaps accommodative reflexes, although no change in light intensity has taken place. Altogether, the mental and physical condition of patients with field defects resulting from brain tumors is usually such as to inhibit the individual attention necessary for trustworthy observations with entopic method.

With the objective method, the monocular pupillometer being used, the main difficulty arises from the amount of light necessary to give a good view of the pupil. This degree of illumination is about the same in amount whether it be from the light in a pupillometer such as described in the previous paper,² or whether it be daylight or light from any source whatever, and the amount is such that as soon as the pupil is properly illuminated, it is at the same time markedly contracted. Under these conditions when a certain increment of light is added to the light already strongly contracting a pupil, the reaction may be hardly perceptible, while if the same increment of light is thrown on a dark adapted retina the reaction will be very noticeable. If the test lights used on the other eye are not of considerable strength, the stimulation may not be, in certain cases, sufficient to travel the consensual route and override the strong stimulation already present in the consensual eye sufficiently to

give reactions that can be interpreted as other than equivocal or negative.

The logical sequence of these considerations was the desire to construct an instrument which would utilize the same light, necessary in any case for observation of the pupil, also to perform the hemiopic pupillary test. In addition to these requirements other desirable conditions to be fulfilled would be the possibility of varying the size of the areas symmetrically within all necessary limits and of rotating either area about the point of fixation from the blind to the seeing field. Further, both lights should be under complete control so that the intensity of either one could be varied above or below or made exactly equal to that of the other, or that the intensity of both could be varied together without disturbing the ratio of intensity between them. Such an instrument would also come much nearer satisfying the demands of a routine clinical instrument since the usual pupillometer trappings could be dispensed with, or used at will, and the pupillary reflex directly observed. Accordingly, somewhat over a year ago an instrument, of which a description follows, was constructed to meet, as well as possible, the imposed conditions.

THE NEW INSTRUMENT

A diagram of the necessary light control is shown in Figure 1. The lights, *AA'*, are new 60-watt tungsten filament lamps selected from a large stock as nearly equal in all measurements as possible. From the wiring scheme it will be seen that they are connected in parallel. One side of each is directly connected to one side of the house current (110 volts). The other side of each lamp is likewise connected to the other side of the house current but must first travel through a set of resistances. The whole current first passes through a rheostat, *B*, whereby it may be varied in five steps from nothing to full strength. From the rheostat, the current then passes to the fixed bar of the sliding contact, *E*. This sliding contact, together with similar contacts *D* and *F*, may be moved laterally in contact with the edge of a slate slab *C* measuring 1 by 12 by 8 inches and wrapped with No. 26 B & S gage (0.016 inch diameter) German silver wire, the interval between the turns of the coil being about 0.2 cm. This size of wire was found by experiment to have the necessary resistance to regulate the individual lamps, and still would not burn out under the contacts, with ordinary care. From the contact the current divides, passing through a variable amount of resistance to contacts *D* and *F*, and thence through their individual fixed bars, and on to their respective lamps. If now we wish to decrease the intensity of the light *A*, we have simply to move the contact *D* farther out or to decrease *A'* to move the contact *F* farther out. If now with either of these contacts at any distance we wish to produce further change in the relative light intensity, we may simply move the contact *E* between the two contacts *D* and *F* until the desired point is reached without adding extra resistance but merely readjusting that already in use. Thus, if necessary, we can throw the whole or any part of the resistance on the slab *C* into the circuit of either light or divide it between them in any ratio. For purposes of measurement, the slab resistance is divided into ten divisions (points) each way from the center.

These two lights are encased end to end in the diameter of a heavy tin drum of about the size of an

ordinary snare drum (14 inches diameter by 6 inches depth). Access to the interior is allowed by two doors in back. The inner surface of the drum is enameled white, and has two movable partition wings of the same curvature as the circumference so that when not in use they can be made to lie flat against the curvature of the drum. When it is desired to prevent one light from contributing more or less to the other, these wings may be turned inward to a corresponding degree or may be moved until they touch the axle for maximum effect. This axle in the center of the drum is hollow and acts as a hub posteriorly to receive the fixed axle on which the whole drum may be revolved, but anteriorly it has two large holes bored in it to transmit light to the fixation point, and still farther forward acts as an axle for the movable segments of the rotary shutter, which makes up the front of the drum.

The rotary shutter is an elaboration of the same type as that previously described. The segments (Fig. 2) necessary to make up the shutter were cut out of heavy tin, although a similar weight in sheet brass would probably have worked up with less tendency to warp. The first disk, *F*, has two equal openings *L* and *L'*, the shape being such as to give the maximum area for the minimum movement of the shutter. The inner margin of each area is on an arc of 1 inch radius from the center and the outer margin on an arc of $5\frac{1}{2}$ inches from the center, at maximum opening an arc of 45 being subtended. On the quadrants, *E* and *E'* is placed another segment of size and shape to fit the interval left by the next superimposed segment *G*. Thus a smooth surface is provided for the shutter to move on below, and above the proper level is obtained on which to solder an overhang under which the shutter may pass and give a light-tight closing. The back of this disk carries two plates of milk glass covering the openings. The anterior end of the hollow axle also has a milk-glass window on which is marked a letter *A* and a dot, serving as a fixation point.

The next superimposed segment, *G*, serves mainly the purpose of symmetrically regulating the size of the lighted areas, but at the same time it carries two circular arms extending along the outer margins of the lighted areas, forming a smooth course on which the edge of the shutter may travel under cover of another overhang providing a light-tight margin. This disk is not fixed to the drum as the first one is, but is free to rotate when the clamps holding it to the first disk are loosened. The shutter is a semi-circular disk, *B*, actuated by a jointed hand lever, as is shown in the assembled shutter *C* drawn in the position where the lighted areas *L* and *L'* have been cut down to about one half their full size.

To eliminate any asymmetry that may be due to reflection from the patient's face, a wide, short cone, truncated to fit the patient's eye, is provided on an adjustable support, so that the distance from the fixation point can be varied within any desirable limits, from 10 to 20 inches usually giving satisfactory illumination. A patient in position before the instrument is shown in Figure 3.

METHOD OF EXAMINATION

Before making any tests, in order to avoid as much as possible any psychic or accommodative changes or any tendency to loss of fixation, the patient is familiarized with the movements of the shutter, until the

shifting of light areas ceases to be of interest. The room is then darkened to exclude all asymmetrical light, and with the shutter at mid-position or entirely open on the blind side, so that light adaptation may be kept equal, or as low as possible before the test is made, the patient is placed in position before the instrument with one eye covered, and the light is gradually increased until the movements of the iris can be accurately followed. This light strength varies slightly, depending on the color of the iris; it is greater for the darker irises. The patient is now told to sit back and close the eyes before proceeding with the observations, in order to increase the dark adaptation, which has a tendency to increase the difference in reaction, and to avoid fixation fatigue. Previously, of course, the lights have been photometrically balanced by means of the sliding contacts and further adjusted to the normal eye so that the pupillary reaction is the same from both lights.

Observation of direct pupillary reactions may be made with the unaided eye, or a short-focus telescope may be used. A very simple aid is made by rolling up a tube of stiff paper which will hold a magnifying glass in one end and fit snugly about the observer's eye at the other end, thus at once cutting out shifting and somewhat confusing illumination on the observer's eye, and enlarging the pupillary movements. This tube may be held in the mid position to avoid asymmetrical reflections. Observation of the consensual pupillary reaction may be effected directly if all light from the instrument is screened off and limited to the eye under examination, by a heavy black conical curtain. Light is then admitted to the room until the movements of the consensual pupil can be followed, but without the use of the curtain the consensual pupillary reaction can also be observed objectively with the monocular pupillometer or subjectively with the entopic pupillometer previously described.

The rate of movement of the shutter has considerable effect on the resulting pupillary reaction. This holds true for the normal eye as well as for the hemianoptic eye. In general, on the normal eye if this change is made slowly from one light to the other no reaction may be noted if the accommodative and psychic reactions are not active. These latter reactions are very noticeable the first time a young person sits down to the instrument and simply fixes attention on the central point. If now the pupil is carefully observed with no change in light distribution one often notices in the course of the first minute or so decided variations in the size of the pupil. A noise or a spoken word may cause a distraction of attention or relaxation of accommodation with corresponding exaggeration of the normal hippus that may be noted for a time in absolute silence. These changes become reduced to a minimum as the patient becomes more and more at ease. In older persons whose accommodative reflexes are no longer active these reactions are much less noticeable if present at all. If a distant fixation point were observed through the hollow axle the condition would doubtless be better if it were not for the liability of the test-lights near at hand to stimulate accommodative reactions as they flash into view.

When these reactions are quiescent there may be no pupillary reaction if the lights are slowly changed, but if the change is suddenly made, we notice a quick pupillary contraction followed by a somewhat slower

dilatation to the former size. This may be repeated on the return change if the interval is two or three seconds or more. As the interval is decreased to the neighborhood of one second or less the pupillary contraction and dilatation becomes less until the interval is of such length that the pupillary reaction apparently does not have time to take place, either on account of the time required for transit of the reflex arc or for light adaptation phenomena. While it might be due to a combination of the two the interval is such as to favor light adaptation as an explanation. Symmetry of distribution on both sides of the macula is not necessary. The same thing happens if the lights are turned into the vertical position and a point a short distance out on the horizontal line through the center is taken as an eccentric fixation point. These reactions obtained on the normal eye are the same from either light when the instrument has been adjusted.⁴ This same reaction may be elicited when the two lights are placed in the seeing field of a hemianoptic eye. But in any case, if the eye is allowed to fix a very short distance—a centimeter or less toward either light, for instance—so that asymmetry enters, a difference in pupillary reaction is noticeable.

In examining hemianopic cases the most satisfactory interval of alternation seems to be that which gives the maximum noticeable pupillary movement and seems to be about the same interval (2 or 3 seconds) as that at which the pupillary bounce is most active in the normal eye. The rate of change from one light to another is made as rapidly as possible for the same reason. In some cases in which the hemiopic pupillary reaction is marked, however, it is difficult to mask it with any kind of a shutter movement. Again, when the reaction is not marked, blinding the macula may be resorted to as a means of intercepting the reaction. A piece of heavy black paper having a circular hole an inch or two in diameter is held over one of the light areas and the patient told to look steadily at the center of this spot of light until looking at the center of the instrument fixation can still be maintained in spite of the blinding.

In order to get an idea of the magnitude of a hemiopic pupillary reaction, aside from measuring the pupillary sizes, two methods were used which gave relative results: first, the amount of resistance necessary to cut one light down to the point at which the reaction was the same from one dim light and one bright light. With the second method, the size of the areas was cut down until the consensual reaction could not be made out with the pupillometer on the other eye with any degree of certainty.

In addition to the use of the shutter with the lights in fixed position one light may be exposed and the whole drum rotated so that the light may pass back and forth from blind to seeing field at constant distance from the point of fixation performing concentric rotation tests, as was mentioned in the last paper. Concentric rotation of one light entirely in the seeing field, however, may give a psychic as well as light adaptation contraction of the pupil; so that this movement must be repeated several times with patients in order to reduce the psychic element as much as possible by thorough familiarization with the procedure.

4. In all cases with eccentric fixation, the shutter movement must be as rapid as possible, for, although the total areas in the mid-position of the shutter are symmetrical, there are two periods of asymmetry during the change before and after the mid-position, but these give stimuli in opposite directions so that the total effect balances well with rapid motion.

Cases with relative central scotomata and vision in the neighborhood of 20/200 can be assisted in fixation by sticking a white paper ring symmetrically around the fixation point. With this aid almost all cases can make out the center. At all events, if there is any tendency to look to one side of the center, it is of such direction as to reduce and not to increase a hemiopic pupillary reaction.

Fourteen cases of both anterior and posterior lesions were carefully studied. Their histories, examination and field charts are given in full in the transactions of the section and in the author's reprints, but cannot be given here on account of space limitations. The results of this study may be here summarized as follows:

SUMMARY

From a study of these cases it would appear that the idea of using relatively strong symmetrical illumination has not been an unfruitful method of examination for the hemiopic pupillary reaction. In fact, it has been rather disappointingly fruitful from a standpoint of clinical diagnosis, since apparently a very similar type of reaction has been found in cases of both anterior and posterior lesions.

In the most characteristic form of the reaction, there is, with central fixation on the rotary shutter, no pupillary bounce whatever, as light is changed from the seeing to the blind field, with any rate or interval of shutter movement. The pupil simply dilates slowly in the course of two or three seconds, being somewhat more suggestive of a pupil being released from the effects of light adaptation, than of an ordinary pupillary dilatation as usually seen in a light reaction test. On changing back to the seeing field there are two kinds of reaction according to the rate of shutter movement. If the change is slow so that light adaptation may have time to take place to a certain extent, the pupil will slowly contract to a certain size. If, however, the shutter movement is very rapid, the pupil contracts with a sudden jerk to a size smaller than with slow movement, and it dilates as light adaptation comes on, to a size about the same as that with the slow shutter movement. This effect of light adaptation varies with the strength of illumination used, being much more marked with the strong illumination used in direct examination than with the weaker illuminations which may be used in consensual examinations.

In addition to this characteristic type of reaction there are those cases in which there is only a slight pupillary bounce when the light changes to the seeing field, but the pupil is noticeably larger with the light in the blind field than when in the seeing field. Finally, as the reaction becomes equivocal, it is noted that without distinct difference in pupillary size at rest, there is a more marked pupillary bounce on one side than on the other.

These reactions in their various stages have been found in anterior lesions as well as in posterior lesions. Indeed, one of the most striking examples was in a posterior case. The phenomenon has been found in rather early stages of incomplete hemianopsia of both bitemporal and homonymous types. It has been found in tract and chiasmal lesions both with and without relative central scotomata.

The topical diagnosis in the cases presented is without question in the anterior group of chiasmal and tract lesions. In the group of posterior cases the diagnosis is almost as certain, though without necropsy

it would not be possible to say absolutely that there was no involvement of the pupillary tract, or of the primary ganglion centers. In addition to this rather slight ray of hope, there is the possibility in some of the cases that secondary degeneration may have affected the pupillomotor tract as has been suggested by Rothman. In this connection it would be extremely interesting to follow for from six to eighteen months the pupillary reactions in a very early case of hemianopsia due to capsular apoplexy.

Previously we have been contending largely with the problem of dispersion light, but now, having disposed of that problem more or less satisfactorily, we are evidently confronted by a still more serious complication in the retinal properties of light and dark adaptation. One can blind one half of the retina by looking at the edge of a large bright surface and obtain a difference in pupillary reaction in the normal eye with the rotary shutter. Indeed, the action of the normal eye with direct test on the rotary shutter shows the complication of light adaptation. In complete homonymous cases of whatever origin, Cushing has long noted a large pupil in the eye having lost the temporal field, that is, having lost the greater area of active retina. I have seen this phenomenon several times and three such cases are given in this report. Two of them are posterior lesions. This pupillary status appears too constantly for a sympathetic phenomenon and it cannot be explained by assuming all the pupillomotor activity to be resident in a small macular area, nor does it agree with the idea that the reflex pupillary arc is still intact on the blind side in posterior lesions, even if it were known that the pupillomotoric area were quite large and extended farther on the nasal retina. It may be more easily understood when we consider the light and dark adaptive effect of the two unequal retinal areas on their respective pupils.

From the examination of these cases it would appear that the blind retina has, to say the least, either lost or decreased in light and dark adaptive effects on the pupil. If light and dark adaptive pupillary reactions exist merely as a regulating mechanism, and involve the presence of retinal pupillomotor activity, then we are forced to the conclusion that the retina must either be weakly pupillomotoric to a considerable distance from the macula (30 to 40 degrees), or it is pupillomotoric in a small central area which is sufficiently active, when split, to give a difference in reaction to that distance by asymmetry. In either case, the pupillomotoric activity must fail in the blind retina in order to give the results obtained in these examinations. This has occurred, apparently, in posterior cases against rule (obtained from certain rare cases of subjective blindness from posterior lesions with retained pupillary reactions) that hemianoptic posterior lesions do not disturb the pupillomotoric activity of the blind retina. Possibly the rarity of these cases offers an explanation, that is, that the percentage of cases in which the hemiopic retina is left intact pupillomotorically is no greater than in cases of subjective blindness from posterior lesions, where pupillary reaction is retained. However that may be; it seems reasonably certain that the light adaptive properties are sufficiently damaged in posterior cases of hemianopsia to give a pupillary reaction closely simulating the hemiopic reaction of the pupillary reaction of anterior cases.

Aside from these difficulties, the possible complication of psychic reactions must also be considered. The concentric movement reflex which I have previously mentioned, and could demonstrate in many of these cases, is doubtless simply a light adaptation phenomenon from which the psychic element may be worn away by repetition. The precautions taken before proceeding to the examination aid considerably in eliminating psychic reactions. But the consistency with which the hemiopic pupillary reaction occurs and may be repeated, argues much against psychic complications of any importance. With good cases which could stand the strain of fixation for a considerable period, I have demonstrated the reaction to chiefs and colleagues time after time, as long as they cared to look at it, and none had difficulty in making it out with the unaided eye.

Indeed, in the most marked cases the reactions are so striking that with rough methods one would expect to find a semblance of the phenomenon, and such has been found to be the case. With a pocket flash-light or an electric ophthalmoscope sufficiently strong to give a good view of the pupil, one can get a distinct though not a marked difference in pupillary reaction whenever, on repeated trials, the light is flashed from roughly symmetrical positions on each side of the fixation point. If two flash-lights are held in symmetrical positions and flashed alternately, the reaction is still better but never as marked, or as constant as with the rotary shutter. The fact that the reaction can be detected in marked cases by rough methods both in the anterior and in the posterior cases has an interesting significance in considering the great variety of results reported by observers using these methods.

If the retina has a low grade of pupillomotoric activity or a combination of light adaptive and pupillomotoric properties to some distance from the macula, as my results seem to show, how may the work of Hess be explained? Hess threw a small light on his own optic disk and obtained no reaction by the entopic method when he moved the light above or below concentric with the macula, on to the seeing retina. In fact, sometimes he obtained a better reaction when he passed from the retina on to the bright blind spot because of more reflected light. It is obvious that if the retina about the blind spot had a pupillomotor sensitiveness practically equal to the stimulation of the macula by reflection from the blind spot itself, then the results of Hess could be obtained in the same manner but for an entirely different reason than he supposed, namely, that the peripheral retina had no pupillomotoric activity. Accordingly the size, shape and illumination of the equal areas of the rotary shutter were designed to get the maximum effect from as large an area of retina as possible, and still keep the dispersion light reaching the macular region constant. With this instrument the reflection from the blind spot simply balances its lack of pupillomotor activity, so that its asymmetrical location apparently has no effect.

Altogether from a careful study of the cases reported herein, apparently many conclusions may be drawn, of which the following would appear particularly justifiable.

CONCLUSIONS

1. A weak hemiopic pupillary reaction may be masked by the pupillometer light when observed consensually.

2. Light and dark adaptive phenomena, in addition to dispersion light, seriously complicate the hemiopic pupillary reaction.

3. The hemiopic pupillary reaction is definitely present in anterior lesions, when examined by the rotary shutter method.

4. The hemiopic pupillary reaction is also present in cases having every clinical evidence of being purely posterior cases, although necropsy examination is necessary to prove absolutely that there is no involvement of the optic tract or primary ganglion centers.

5. Although it may be concluded from the examination of these cases that the peripheral retina does possess a weak pupillomotor sensitiveness, there is no evidence that the hemiopic pupillary reaction has any topical diagnostic value.

I am deeply indebted to Prof. Harvey Cushing not only for kindly facilitating this investigation but also for generously allowing me the privilege of presenting this particular phase of his cases.

223 Charles Street.

ABSTRACT OF DISCUSSION

DR. WALTER B. LANCASTER, Boston: It seems to me that our views of the anatomy and physiology of the pupil reflex paths will have to be revised if these preliminary reports prove to obtain in case of further investigation. We hope that by another year Dr. Walker will have examined enough of these cases to establish certainly whether all posterior lesions as well as the anterior show this phenomenon. He has not attempted to theorize concerning what path the reflex follows. It is an important physiologic problem. Another revolutionary idea which seems to follow from Dr. Walker's experiments, is that the periphery of the retina as far at least as 30 degrees, has the pupillomotoric function as well as the central region. Hess would limit the pupillomotoric area to the central 15 degrees only. I think this a good time to say something in appreciation to Dr. Todd's recommendation for research work. It might appear that this piece of research work was in vain, because this symptom is proved to be of no diagnostic value; but the necessary knowledge of the literature and the exhaustive study of the various factors that come into this problem cannot fail to be of decided value in solving other problems the worker is sure to meet in practice. Of course the importance of proving that the Wernicke symptom has no diagnostic value is obvious.

SAFE AND SPEEDY EXTRACTION OF THE IMMATURE CATARACTOUS LENS FOLLOWING PRELIMINARY CAPSULOTOMY*

HOMER E. SMITH, M.D.

NORWICH, N. Y.

The contentions embodied in this thesis are:

1. An ample, properly executed preliminary capsulotomy has, in mature cataracts, many advantages over immediate capsulotomy or capsulectomy.

2. In morgagnian cataract it enables one to make what is difficult otherwise, namely, an efficient opening in the capsule.

3. The extraction of the clear lens in high myopia is feasible by this method, and

* Read before the Section on Ophthalmology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

4. It will render immature cataract operable after a six-hour interval, leading up to a clean extraction.

These contentions are submitted in the foregoing order that their correlated value may be presented and that the subject-title shall receive final and full consideration. It is generally stated by most writers that the lens-capsule is a highly elastic membrane which, on section, curls outward. It is very doubtful if this statement be true; not as to its curling outward, which is thought to be due to another cause, but as to its elasticity. If it were elastic and under tension it would gape only to incisions at right angles to the lines of traction; that a crucial incision should gape would require elastic fibers radially disposed. This is simply a matter of physics. There is nothing to show histologically the presence of elastic tissue in the lens-capsule; on the contrary, it is a homogeneous hyaline structure which does not stain, nor has the most searching microscopic examination shown elastic fibers therein. Neither can the gaping of the capsulotomy wound be explained on the basis of inherent elasticity in the lens fibers themselves. To quote Tscherning, "The contents of the crystalline lens are composed, in the adult, of two parts: the nucleus, which cannot change its form, and the superficial layer which, on the contrary, possesses this faculty to a very high degree; its consistence is very nearly that of a solution of very thick gum." Quoting Hocquard, he continues, "The whole is surrounded by a capsule which is inextensible or very nearly so. In fact, the laws of dynamics and of finely coordinated muscular action elsewhere in the body demand that, for accommodation, the lens capsule shall be inelastic." In an address delivered in the University of Oxford, Sir William Job Collins says:

The lens is truly described as very elastic in the sense of readily tending to resume its original form after the withdrawal of any force that has modified its form or volume. I should not be disposed to allow that the same elasticity is true of its capsule, though this is alleged by most authors. From a study of it in dissection and in operations, I should be more disposed to say, with Bowman, it is "a hard and dense structure and determines the exact outline of the lens." The capsule is composed of albuminoid substance not of elastic tissue and betrays no trace of cellular structure; on laceration it gapes and sometimes curls in a fashion suggesting that it is held taut by the reefing lines that bind it to the ciliary processes. [Italics mine.—H. E. S.]

Underlying the anterior capsule of the lens and forming with it an intimate union is the epithelial layer whose cells by elongation become lens fibers. The well-known reproductive faculty inherent in these cells, and that any epithelial residue left clinging to the capsule may by proliferation produce a secondary membrane, make imperative that as little as possible of this be left in the eye. A close examination of secondary cataracts will disclose a small opening in the capsule, lens matter at the periphery of the pupil and growing out into this new lens fibers in the visual aperture. Incidentally, this is one of the arguments against a capsulectomy. The foregoing, relative to the capsule, is germane to what shall follow when technique is taken up, to the explanation of what changes take place in the interval between capsulotomy and the extraction proper and to the question why, to secure such altered relationship, an ample capsulotomy is necessary. Reference to these will later be made.

A historical review of the operation of primary capsule rupture need not here be made, for Dr. Percy Fridenberg¹ has so exhaustively covered the ground in a paper read before this Section in 1912 that he leaves nothing to be added. I shall, however, avail myself of frequent quotations from this paper to adduce arguments in support of my several contentions.

It is a reasonable assumption that the lens-capsule is more or less adherent to the epithelial layer immediately beneath it; that it is non-elastic; that it is the traction of the reefing lines that causes it to gape when divided, and that, in proportion to the amplitude of such division, it will release itself from the underlying cortex. With no knowledge of the work of earlier investigators I worked out for myself many years ago a method of preliminary capsulotomy which had for its objects a knowledge in advance of the size of the corneal section to be required for an easy exit of the lens and to make certain an ample and sufficient capsulotomy with the maximum of precision and the minimum of risk. At this time the knife-needle of Knapp was being used but, finding with this that the making of the second limb of the crucial incision became next to impossible, because of early loss of aqueous and the obliteration of the anterior chamber, I supplanted it by a miniature scalpel of my own design which obviated this difficulty. A sketch of this is here inserted (Fig. 1).

I have in former papers gone over the matter to follow, but larger experience only makes more certain

Fig. 1.—The capsulotomy knife.

the truth of the statements therein contained. To restate them: The advantages of a preliminary capsulotomy are many. By the ordinary method some of the difficulties are inherent in the instrument itself, but more and greater ones in the conditions under which it must be used. The straight capsulotome is kept sharp with difficulty. It cuts only when drawn toward the operator; at right angles to this it simply scratches. As soon as the section is made the iris contracts, the lens comes forward and the anterior chamber is abolished. Into this narrow space must be passed a straight instrument between cornea and lens; it is impossible to do this and reach below the anterior pole of the lens without pressing it more or less backward, and at this stage the lens, held only by its suspensory ligament, is mobile and easily dislocated. More than this, the operator in his zeal to make an efficient opening in the capsule is apt to rupture this ligament, and loss of vitreous ensues. There are no means of knowing that the capsulotomy has been inadequately performed until the lens, when pressure is applied to the globe, refuses to come forward. In this event, either the fixation forceps must be reapplied, a difficult and dangerous thing to do on an opened eye, or the cystotome reintroduced without its help, in the trust that the patient will keep still. Narrowing of the pupillary space by the contraction of the iris leaves insufficient room in which to work, and it is a difficult matter not to

1. Fridenberg, Percy: Preparatory Capsulotomy in Extraction of Immature Senile Cataract, THE JOURNAL A. M. A., Sept. 21, 1912, p. 1065.

wound it or entangle it in the tip of the instrument. If the bent cystotome of Knapp is used, these difficulties are enhanced, and not only are there greater obstacles to removing cortical fragments, but a periphereal capsulotomy leaves two thicknesses of capsule in the pupillary space and more often a secondary operation is required. Should blood enter the anterior chamber, the difficulties mentioned before are further increased. None of these difficulties accompanies a preliminary capsulotomy as described in this paper: 1. The knife can be made superlatively sharp, and efficiently cuts the capsule in both directions. 2. Only through the grossest carelessness can the suspensory ligament be ruptured or the lens dislocated, for this is held firmly in place by the vitreous behind and the aqueous in front. 3. Ample space is given through the dilated pupil, and the point of the knife may be kept fully in view during the division of the capsule, and, furthermore, the operator has the satisfaction of knowing that this is adequately performed. 4. The iris cannot be wounded or entangled in the instrument, and there can be no bleeding to obscure the field of operation. In brief, it simplifies and makes certain a step in the operation which is usually fraught with difficulties and dangers. Also when the corneal section comes to be made the iris does not contract so readily, and there is less interference with the extrusion of the lens. It has the further advantage that one can tell in advance of the section just how large this needs to be. If the cut in the capsule is practically invisible, a large nucleus is present. If semigelatinous matter exudes, it is smaller, and if a milky liquid it is smaller still. It is an extremely difficult, if not impossible, task to estimate, with any degree of accuracy, from ophthalmoscopic examination alone, just what is the condition of cortex and nucleus in a cataractous lens, mature or immature. Preliminary capsulotomy reveals the matter and puts us on our guard in some cases. If gelatinous matter exudes we have a soft cortex and probably adherent lens fibers. This is true even if the opacity extends clear up to the anterior capsule and where we would be led to expect, *a priori*, a clean exit of the lens. With an ordinary capsulotomy this means a mushy extraction and much lens matter left in the eye. Even if no operative accident occurs and a nice clear black pupil is secured, the appearance of the eye at the first dressing tells the lamentable tale. Here comes in the advantage of the six-hour interval before the extraction. The action of the aqueous separates the adherent cortical fibers from the capsule, and a clean extraction follows. It is truly marvelous how little pressure is needed to deliver the lens; often it follows the knife on completion of the section. Several operators have written me that this unexpected result was somewhat embarrassing, but it need not be so if it is anticipated. In operating on a morgagnian cataract by the usual method difficulties arise because, on essaying the capsulotomy, the instant the point of the instrument penetrates the capsule the liquid cortex escapes through the puncture, and before this can be extended to an incision, the sac collapses, recedes from the instrument, no further opening is made and there remains in the eye the nucleus in its capsular envelope with an aperture therein too small to admit of its exit. Nothing safely can be done in the way of a more extensive capsular laceration, as the collapsed sac recedes from the point of the cys-

totome. There is a relaxed zonula, no traction on the capsule, and there remains for further instrumentation only that with the sharp hook or the Daviel spoon. It is not necessary to dwell on the operative difficulties which must then be faced or the dangers to the integrity of the eye. With a preliminary capsulotomy the fluid cortex simply mingles with the aqueous, the sac does not collapse or recede, there is no difficulty in making an ample opening, and at leisure we may observe the size of the nucleus and proportion the extent of the corneal incision for its easy exit. The section may then be made with the angular keratome, and at once if it is so desired. There is no advantage to be gained by waiting in morgagnian cataract, for there is no longer cortex to be dealt with. An operative point is here apropos for such cases and for those in which a primary capsule rupture is to be made instead of the usual capsulotomy. It occasionally happens that sufficient aqueous escapes through the corneal puncture to make the anterior chamber so shallow that section would be difficult. In this event, the tip of the McKeown irrigator is applied to the corneal opening and the anterior chamber filled out with normal salt solution. The operation may then proceed as though this incident had not occurred. It does not need any argument to prove that the smaller the corneal section consistent with an easy exit of the lens, the better are the patient's chances against infection and for an uninterrupted healing of the wound, to say nothing of the larger probability of the surgeon making this in a single plane and with greater facility.

It is conceded that operative difficulties and post-operative dangers attend the removal of a cataractous lens in which there is still much transparent cortex; also, it is certain that a method which would minimize these dangers would be of inestimable value to both surgeon and patient. It is also true that it would be better still if all media could be removed which are opaque or which might become so, provided always that in so doing no greater risks, immediate or remote, are incurred. Given a case in which, from advancing opacity in the lens, there results diminished visual acuity, industrial incapacity and mental distress, several courses are open to us. We may advise, as was formerly the almost universal rule, that the patient wait until complete opacification occurs and the cataract becomes operable. This meant for the sufferer more mental distress, a gradually lessened earning capacity, perhaps even poverty and the loss of all the pleasures of life which are dependent on good vision. To make matters worse, there was the haunting element of uncertainty, for no man could say how long might be the weary waiting, or whether after years of groping in semidarkness, even then operable maturity would result. The second course open would be an extraction after the usual method, with all its attendant dangers, operative and post-operative, and the rather small chance of a final good visual result. The third choice would be artificial induction of operable maturity by Förster's, McKeown's or some other method; the fourth, extraction in the capsule, and the last, safe and speedy extraction by my own method.

It is in the hope that the first shall be last and the last shall be first of these several choices, that this paper is presented for your consideration.

Against the second course the profession is practically united, although it is true that in highly skilled hands, with irrigation to remove cortical debris, with preliminary iridectomy and subsequent needling, a fair proportion of successes may be attained; but no one will deny that the risks are greater, the convalescence more prolonged and the final visual results poorer than would be the case in mature, operable and fully opaque cataract.

The third course is artificial maturation; operations intended for this purpose have not attained success and have fallen into disuse. None of the methods used seem to produce any uniform or decided effect. Puncture of the capsule advised by von Graefe in 1864 and reintroduced by Correnti in 1872 fails for the reason that punctures in the capsule do not gape, and there are formed (if any effect is produced) simply insulae of opacity just beneath them and no separation between capsule and cortex. McKeown injected fluid under the lens-capsule. This procedure, though successful, was difficult and dangerous. Does it not seem more rational to bare the lens of its capsule and let the fluids of the eye itself do this effective work?

The fourth course we might follow is extraction in the capsule: against this much must be said. If it could be done with the same proportion of immediate or ultimate successes or with no greater operative risks, this method would be ideal, for it removes in one step every impediment to the clear passage of light into the eye. Unfortunately, the operative risks are appalling and only in hands especially trained under personal tutelage of its one able exponent are these, even then, brought within reasonable comparison of the time-tried classic methods. Barring operative accidents, the immediate results are brilliant; but there are the later ones to be considered. The updrawn pupil (in spite of the large iridectomy) which is later present in these cases points to a dislocation of the vitreous, and I am credibly informed by surgeons of the highest authority in India that there is a slow degenerative change which takes place in these eyes and ultimately leads to much loss of vision. On theoretical grounds the procedure is harsh and unsurgical. To use force sufficient to rupture the zonula, applied from behind (for the resultant force must come from this direction) even if there results no loss of vitreous, is in my opinion a damaging traumatism and a menace to the future integrity of the eye. I have done successful extractions in the capsule, but they were operative mistakes following an insufficient capsulotomy by the usual method. In skilled hands it might possibly be the operation of choice where there was a deep anterior chamber and a tremulous iris, for here one has a weakened zonula; but as a routine measure or for the occasional operator it has my unqualified disapproval. I have had no experience with the manner of separating the lens from its zonular attachment by any of these four methods, namely, suction, traction, lateral pressure or rotation in the patellar fossa; of these the latter appeals to me as more likely to attain the desired result with a minimum of traumatism.

This reviews other methods of dealing with immature cataracts; in my own the capsule is opened by as large a crucial incision as it is possible to make, done as a preliminary measure six hours before the extraction proper. In my own experience, confirmed

by that of others, this is sufficient to produce almost invariably a complete separation between capsule and cortex, to make operable cataracts in any stage of maturity leading up to a clean extraction and rarely leaving cortex behind. It has long been my conviction that the extraction of the clear lens in high myopia was feasible by this method, but I had no opportunity to test this personally. In six of the cases analyzed later in this paper it was carried out and all were successful. One could put the procedure to no greater test than this, for surely, if it led up to a facile extraction in these cases, it should not fail if the lens is becoming opaque. No originality is claimed for the preliminary capsulotomy, and whatever merit the method may possess lies in the technic, which is original, and the discovery that immature cataracts may be rendered safely operable in a few hours. If the capsule is inelastic and held taut by the insertion into it of the reefing lines of the zonula, it follows that in proportion as the incision into this is nearer the point of insertion of these lines, the greater will be the retraction; and the more nearly this incision approaches in form an equal-armed cross, the more perfectly will the capsule retract from the lens

Fig. 2.—Operator standing at patient's head. First plane. Section through right eye on a plane parallel to the long axis of the body. The blade piercing the cornea at *x* is passed down to the lower margin of the dilated pupil and brought successively through positions *B*, *C*, *D* and *E*, thereby effecting a long vertical cut in the lens capsule.

surface, leaving it open to the imbibition of aqueous. Assuming this to be true, it follows that the technic which will insure this large opening is a matter of importance.

It is a matter of difficulty to convey clearly in words such a description of even the simplest operative procedure that he who reads may run—and do it in like fashion. This has been brought home to me by much correspondence from those to whom my previous descriptions were not clear. To this I have appended illustrations which I trust may help to clarify whatever may be lacking in the written word.

In the first place, the shape of the knife is important if one is to make with it the necessary excursions in the anterior chamber and not get into trouble. The blade length should be 2 mm., the belly rounded, the point obtusely ground and the whole acutely sharp from end to end, for heel, belly and point must successively come into use as the cut progresses.

The pupil having been fully dilated by a 2 per cent. solution of homatropin, the proper preparations of

asepsis and cocaineization carried out and the speculum inserted, the operator, if for the right eye, takes his place at the head of the patient. Taking a large grasp with the fixation-forceps over the insertion of the internal rectus, with the little and ring fingers resting on the patient's temple, the capsulotomy knife, held as a pen with the cutting edge of the blade downward, is thrust through the middle of the supertemporal quadrant of the cornea, pushed away from the operator through the anterior chamber until the blade reaches the lowest possible point of the dilated pupil and rests on the vertical meridian of the lens; the handle is now raised until the blade penetrates the capsule; the handle is then made to describe an arc of a circle away from the operator, the blade cutting the capsule along the vertical meridian of the lens. To avoid sinking deeply into the lens or producing a dislocation, the shank is gradually withdrawn in describing the arc until at the termination of the cut

Fig. 3.—Operator standing at patient's head. Second plane. Section through right eye on a plane at right angles to long axis of body. The blade withdrawn from position at *E* (first plane) is passed to the nasal side (*N*) of the dilated pupil and brought successively through positions *F*, *G*, *H* and *I*, thereby effecting a long cut in the lens capsule at right angles to the first incision.

little more than the blade remains within the eye. The point is now released, the handle brought into its original position, the shank reintroduced and the blade carried over to the margin of the pupil nasalward and onto the horizontal meridian of the lens; the handle is now given a quarter turn toward the operator, thus bringing the cutting surface of the blade against the capsule. Again is the handle made to describe the arc of a circle, this time nasalward, the blade being kept on the horizontal meridian of the lens and the shank gradually withdrawn as the cut approaches completion. The blade is then brought into its original plane of entrance (to avoid enlarging the corneal wound) and withdrawn from the eye. If for the left eye, the operator stands at his patient's left, the corneal entrance is in the temporo-inferior quadrant and the first cut in the capsule begins above on the vertical meridian of the lens, ending below. Otherwise, the technic is the same. The speculum is now removed, a drop of physostigmin (eserin) solu-

tion, $1\frac{1}{2}$ grains to the ounce, is dropped into the eye and an antiseptic dressing is applied.

It is evident that on the spherical curve of the lens surface the cut begins with the heel of the blade, is continued with the belly and ends with the point—hence the shape of the blade and the need for cutting sharpness all along its length. That the blade be short is necessary if the proper maneuvers in the anterior chamber are to be made without enlarging the corneal wound, without dislocating the lens, without having loss of aqueous, without cutting too deeply into the lens substance; it is necessary also to success in making the largest possible capsulotomy.

With the ordinary knife-needle, to escape these dangers, only a small crucial capsulotomy is possible. If aqueous is lost while the vertical cut is being made, the transverse one is impossible. If my assumptions of the mechanism of the rapid operability of immature cataracts and the retraction of the capsule be true, then it is essential that the technic here set forth be accurately followed.

Six hours after the capsulotomy the extraction proper is undertaken. I had formerly advised a twenty-four-hour interval, but I fear that this was more from motives of convenience than of necessity. Moreover I could not see that the lens came out any easier in this than in the lesser interval. On two occasions, with the longer waiting, high tension was a complicating factor in the extraction. This has occurred also in the shorter period to other operators, but, while introducing difficulties, has not resulted disastrously, as the extraction has checked the process. Occasionally, some circumcorneal injection was manifest when the dressings were taken off for the second operation. In these cases, to insure proper anesthesia, the cocaine was preceded by a drop of 1:1,000 epinephrin solution. The extraction proper is done after the usual method, but the operator now knows just how large a corneal section is necessary. If there has been no escape of semigelatinous lens matter from the capsular cut, then the section should comprise the upper two-fifths of the cornea, as the nuclei of immature cataracts are usually large.

Each operator may elect whether or not he shall make a conjunctival flap. My own preference is for this and a large one. Here, again, is another advantage in preliminary capsulotomy. The flap turned down over the cornea, when an ordinary capsulotomy is next to be done, obscures the operative field. When this has been done, the disposition of the flap is no embarrassment.

The matter of simple versus combined extraction is too complex to admit of review in this place. My own choice is for the former, provided the iris is mobile and dilatable. The cosmetic results are better, and there is no risk of adhesions between cut iris surfaces and tags of capsular membrane. With preliminary capsulotomy there is practically never cortical debris to be reckoned with, and the risk of iris prolapse is minimized by the immediate use of atropin following the toilet of the wound. There are surgeons, however, who prefer the combined extraction as a routine procedure. There is much to be said in its favor, and for the occasional operator who has not the facilities of special hospitals or trained ophthalmic nursing it is perhaps the safer method. That the contentions embodied in this thesis might carry greater weight than would my own unsupported asser-

tions, letters were sent out to members of this Section, whose replies are tabulated here.

RESULTS OF OPERATIONS ON IMMATURE CATARACTS
FOLLOWING PRELIMINARY CAPSULOTOMY

	No.	Per Cent.
Total number.....	180	..
Of these there were successful.....	164	91
Total failures.....	5	3
Partial failures.....	11	6

There were thirty-nine operators who reported cases; of these several reported only one case each. Taking into account unfamiliarity with a new procedure at the hands of many men, and comparing the statistics of results in fully mature and operable cataracts with the percentages here given, in what is admittedly a more difficult and dangerous operation, it will be seen that this method does not suffer by comparison. An analysis of the causes for partial and total failures would make the comparison still better, for of the total failures one had nothing to do with the operation, and the partial failures were tabulated as such irrespective of the final visual results. Of the five total failures, one was due to intra-ocular hemorrhage some days after a successful extraction, with no ascertainable cause; one was due to vitreous prolapse, the nucleus being left in the eye, which was subsequently lost by plastic iridocyclitis; one was due to plastic iritis; the pupil closed in and two cystotomies later failed to keep it open. For the remaining two no cause was given. Of the partial failures eight were due to lens matter left in the eye; in one case the operator failed in technic only, the final visual result being good. No cause was given in two cases. Final results were good in three cases, and not reported in eight. Of operative accidents only three are reported; in two the lens was dislocated, and in the third partially so. There were twelve cases reported of postoperative complications; six of these were iridic inflammations, six of high tension; but while these introduced an embarrassing feature, none resulted disastrously. The intervals between capsulotomy and the extraction varied between six hours and ten days, the largest number being twenty-four hours.

Against the many advantages of a preliminary capsulotomy, irrespective of the maturative process on the partially opaque lens, I advanced the objection that the operation requires more time and trouble, as the technic of asepsis must twice be gone over. Dr. Fridenberg says, "We cannot, however, dismiss all objections in a single sentence unless we close our eyes to the fact that it is the danger of infection even more than the time and trouble of disinfection in a second operation to which we hesitate to expose our patient and which we or for not risk unless there is something definitely justified." I am not aware of any experience with the manner of action under modern methods, namely, suction, traction, maller than in the or rotation in the patellar fossa; of for in this it was appeals to me as more likely to attract infections at all. result with a minimum of traumatism in a single This reviews other methods of dealing with immature cataracts; in my own the capsulogical procedure, as large a crucial incision as it is possible to make, done as a preliminary measure six hours before a section one extraction proper. In my own experience with capsulotomy

if properly performed, nor is there need of this, for there remains no capsule in the pupillary space. In the circular letter sent out criticism was invited. The most serious objection was that high tension followed. This occurred in 3 per cent. of the operations. In such cases it is better not to use a speculum but to employ Angelucci's fixation. Also, the section should end with extreme gentleness, as the lens will almost invariably come out with its completion. The next objection in point of importance was retention of lens matter at the time of extraction. This occurred in less than 5 per cent. of the cases. This, too, compares favorably with the percentage of the same mishap in apparently fully mature lens extractions. It usually can be successfully met by irrigations with McKeown's instrument, using normal salt solution; failing the accomplishment by this, needling should give better vision. There are cases which will always require this, for, quoting Risley, "In this class of cases there is usually some involvement of the posterior capsule as a sequel to the uveal disease which caused the cataract, and secondary capsulotomies are frequently required."

It should not be forgotten that a cataractous eye is a sick eye and perfect visual results the exception and not the rule. Two well-known surgeons have written me that they could not see that the lens comes out any easier or cleaner with a preliminary capsulotomy than without. If this be true, why the many procedures which have been adopted for the artificial maturation of the opacifying lens? Why have surgeons hesitated to operate on immature cataracts? Or why should this paper have been written at all? Many of my colleagues have been so good as to express their commendation. They say:

"It is a valuable addition to our technic, the best since McKeown gave us the irrigator."

"Approve of it very much and favor it especially after having had some experience with the Indian Smith operation."

"Consider your method, if carefully performed, devoid of danger and superior to other methods of hastening the maturity of unripe cataracts."

"The intracapsular operation is still the thing we most desire, but if the capsule of the lens is to be left within the eye, there is no operation which compares with yours."

"Believe this is one of the best, if not the very best, operation for immature cataracts."

"Have found the procedure very satisfactory."

"A safer operation than extraction in the capsule."

"Think it good practice and expect to use it more."

"Believe it to be superior to Förster's."

"I am much impressed with the great value of your procedure. For immature cataract, especially in subjects under 55 years of age, in conjunction with irrigation of the anterior chamber it appeals to me to be unexcelled."

These opinions, selected from many others equally commendatory, are from men eminent in the profession and known to all of you.

In conclusion, I wish again to emphasize the advantages of a preliminary capsulotomy as against capsulectomy or that immediately preceding the delivery of the lens. When properly performed and an interval of six hours allowed to elapse between this and the extraction proper, a separation between capsule and cortex will result and so make immediately operable cataracts in any state of opacification; and the delivery of the lens, mature or immature, is cleaner and easier than by any other method.

ABSTRACT OF DISCUSSION

DR. S. D. RISLEY, Philadelphia: I have been able to demonstrate to my own satisfaction the signal value of preliminary capsulotomy in the several varieties of immature cataract, but have not employed it, as Dr. Smith suggests, as a preliminary step in the extraction of fully opaque lenses. In the extraction of mature cataract I have not experienced the difficulty and danger he describes in performing capsulotomy after the corneoscleral section has been made. The procedure, however, in lamellar cataract, extraction of the lens in high myopia and the amber-colored and posterior polar or capsular cataracts, has proved valuable. In the opaque, milky lenses of the morgagnian type, I doubt its expediency unless the remaining nucleus is extracted immediately. I have been led to fear the deleterious influence of the contents of the capsule of a fluid cataract on the health of the eye if allowed to escape into the anterior chamber and remain there. The eye is liable to ciliary injection or iridocyclitis with

capsulotomy is important.

To cut deeply into the capsule is the operation. The

perform the cross-section of the capsule, being careful to avoid the nucleus. I have used for this purpose a fine needle described some years ago, a

thin midrib beaten from a piece of wire, which can be made so that the blade is tightly filled with the substance of the lens. When this blade is

used at first only a dark line of illumination to broaden into a capsule which later becomes opaque. This grayness has passed

found it convenient to under-ride the lens in six hours after the preliminary capsulotomy, but have habitually allowed two days to intervene, unless necessity arose for earlier intervention. In my experience, no untoward results have come from this delay provided the anterior cortex of the lens has not been deeply invaded while cutting the capsule.

At my Wills Hospital Clinic I have to contend with a large percentage of complicated cataracts, that is to say, eyes with uveal disease with vitreous infiltration, irises which do not dilate well, engorged anterior ciliary vessels and opacities of the lens, or opacity of the posterior capsule, often spreading to the cortex at the pole of the lens, with or without spicules emanating from the periphery of the lens and projecting along both the anterior and posterior capsules into the pupillary area. In a considerable percentage of these eyes the lens becomes amber-colored, remains more or less transparent and the opacity does not advance. In these cases I have found the preliminary capsulotomy of advantage. I have not been so fortunate as Dr. Smith seems to have been in extracting these lenses without the necessity for secondary operations. I have been compelled in certain cases to resort to secondary capsulotomy to secure a clear pupil. The procedure is of signal advantage in the extraction of the transparent lens in high myopia and in the lamellar cataracts of childhood. I am convinced that in the entire group of cases which I have designated as complicated cataracts, the preliminary capsulotomy affords better results than can usually be obtained by extraction by our more usual methods.

DR. HIRAM WOODS, Baltimore, Md.: I have to relate my experience with three cases of the Homer Smith operation. The first patient was a man with double cataract. He was a railroad man, aged 43, whose central vision was reduced to about 3/200 from nuclear cataracts. He was unable to work. I had read Smith's communication. I obtained his knife, and in my first case did a preliminary capsulotomy on one eye, in the afternoon, Jan. 7, 1913. The capsulotomy

was done with the incisions described by Smith. I did not see the patient again until the next afternoon; but at about 10 a. m. that morning I had a message from the nurse at the hospital that the man had a great deal of pain and nausea. In the afternoon I found T+ with the fingers. It was not measured with the tonometer. I made an immediate extraction of the lens. The appearance of the lens had not been changed, but the iris was distinctly bulging forward. The only complication was a rather profuse hemorrhage with the iridectomy. The patient recovered without further incident. The pupil was entirely clear of any remnants of soft substance, and he obtained 20/20 vision in that eye. Two weeks later, preliminary capsulotomy was done on the other eye at 8 a. m. Early in the afternoon, the cataract was removed with an iridectomy. I followed Smith's directions accurately, allowing six or seven hours between the two operations. There was no reaction and no soft substance. When I last saw the patient, he had normal vision in both eyes. The third case was that of a man aged 40, who had lost one eye from a cataract operation in another city, and I wanted to give him every possible chance. He had an opalescent cataract, V. = 20/200. I did a preliminary iridectomy Jan. 16, 1913, and waited till February 13, and then did a preliminary capsulotomy in the morning, intending to extract the lens in the afternoon. He felt unwell in the afternoon, but the eye was quiet. He grew worse and apparently had an attack of grip. I had to wait nine days, to February 22, before I could remove the cataract. The eye showed no irritation during this time, and when extraction was done, the lens came away readily, leaving a clear pupil. He obtained almost 20/20 vision. These cases bore out Smith's contention that this operation brings away the entire lens. I want to compare these cases with another operated on recently. A woman with an old central choroiditis wanted an immature, nuclear and probably secondary cataract removed. Owing to circumstances, which I could not control, she did not come in time for a preliminary capsulotomy and I extracted the partially clear lens without the preliminary capsulotomy. I had done a preliminary iridectomy two months before. In this case, there was a lot of soft lens substance which had to be removed by irrigation. The patient did well, but had only 20/80 vision from 20/200.

These cases seem to bear out Smith's statement that preliminary capsulotomy is efficacious in separating soft cortical substance from the capsule, and making it adhere to the lens. In the first three cases I had no cortical matter to deal with. In the case in which the preliminary capsulotomy was not done, there was considerable soft lens substance.

DR. ALLEN GREENWOOD, Boston: I have operated in two of these cases of high myopia with nuclear cataract, and have made, instead of the two punctures, a V-shaped incision with a knife recommended two years ago by Dr. Fridenberg. This can be done without the loss of aqueous, and I can testify to the ease with which the lens can be pressed out after this preliminary capsulotomy. It is my custom to do the preliminary capsulotomy late in the afternoon of one day and to operate the next morning, having an irrigating apparatus ready to use if necessary.

DR. W. E. LAMBERT, New York: I have had some experience with the Smith method in cases of high myopia. It is my custom, however, in such cases, to do the ordinary dissection, especially in young people. I operated on a woman over 50, with high myopia and immature cataracts, the nuclei apparently rather large. I did a preliminary iridectomy in both eyes and felt justified subsequently in doing a simple extraction in one eye. The result was most satisfactory; but there was so much soft matter remaining that I did a preliminary capsulotomy on the second eye. A peculiar and alarming complication arose. I have never extracted the lens as soon as six hours after the capsulotomy, but usually twenty-four hours—frequently, in cases of myopia, much later. In the case referred to, forty-eight hours elapsed and the lens being somewhat swollen, I had to make the extraction; a smear, he

showed a mild infection, and Dr. Dixon, our pathologist, advised waiting. I did wait fortunately, and the next morning the patient had an acute mucopurulent conjunctivitis, tension plus, and circumcorneal injection. I used a 1/20 grain of silver nitrate irrigation. At the end of three days the acute catarrhal conjunctivitis had subsided and I extracted the lens. It came out nicely, with less soft lens matter than in the first case. The patient made an excellent recovery. I think the procedure is useful in high myopia, especially in older people.

DR. M. FEINGOLD, New Orleans: I have performed Dr. Smith's operation in about twelve cases, but I had to deviate from the practice advocated by Dr. Smith as to the time of the second operation, for the reason given by Dr. Risley. Another, a theoretical, reason occurred to me for which we should delay the second operation. We all know that bandaging a comparatively sterile eye after it has been handled with any kind of cleaning material such as soap, mercuric chloride or otherwise, may bring about a low-grade conjunctivitis, which, when the wound is closed, is in no way endangering the good result; but should we attempt to operate on the eye during this conjunctivitis, if in any degree purulent, we might run the risk of producing an infection. For that reason I concluded it would be better to make the incision, wait until removal of the bandages, and then to allow the eye to become normal again and in forty-eight hours or later perform the second operation, provided no important indication for delay has occurred. It is interesting that Dr. Lambert's case brought out one of the possibilities which I had determined theoretically. Another reason for delay which occurred to me is that we might make the primary incision with an instrument that has a little thicker shaft and when we attempt the second operation six hours later, we might get emptying of the anterior chamber before we have entered with the knife, should the patient behave badly, squeeze the eye, etc. For these reasons, especially as infection is so important I thought it worth while to delay the secondary operation, and I have delayed as long as ten days, with no untoward symptoms. As to the point of secondary operations, three or four weeks ago I was compelled to perform a secondary dissection following one of these operations.

DR. OTIS ORENDORFF, Canon City, Colo.: Nowadays we seldom have infection after cataract extraction, and those who do the preliminary iridectomy will have few cases of infection, so that it can be almost disregarded. Delaying this operation for several days or weeks or months is a disadvantage, for the patient has to go into the hospital twice, which a good many of them will not like to do; and it is not necessary. I have not used Dr. Smith's knife, but the knife Dr. Risley speaks of. I have tried the operation for morgagnian cataract and am not pleased with it, because the contents of the lens are let out into the aqueous instead of the aqueous into the lens capsule, which is the object of the operation. Formerly, with a patient in middle life with a diagnosis and prognosis of immature cataract, the inevitable waiting, the industrial incapacity and mental distress was much like a sentence of death and victims became depressed, run down and assumed serious physical as well as mental condition. This is now entirely changed, for preliminary capsulotomy brings these cases into the category of the most hopeful of the deeper diseases of the eye. There is not only the hope of good vision, but it is not now necessary to wait for the ripening of the cataract. I have had a few cases attended with more or less success. One especially shows the typical mental aspect in many of these cases and the encouraging result. A railroad mechanic, healthy except for extreme nervousness, who had lost one eye by accident in infancy, had a slowly advancing cataract in the other eye which compelled him to abandon his former more lucrative positions. Oculists whom he consulted advised further delay, but he declared this meant insanity or worse. He could still count fingers at 10 feet and a fairly good view of the fundus could be had. The patient refused to wait further. A crucial incision in the capsule was made with the needle

knife and to my astonishment the lens followed the knife out of the wound. One year later vision was 15/10 plus with 9 plus 2, axis 165. He has been on the pay-roll ten months, a contented man. My records show a number of slowly developing cataracts in comparatively young people who have only one eye, and a preponderance of cataracts occur in one-eyed people, due probably to the excessive use of the remaining eye. Persons with immature cataract compose a large percentage of our patients, and if this operation will afford them early relief it behooves us to recognize it.

DR. JOHN GREEN, JR., St. Louis: That six hours may be an insufficient interval between preliminary capsulotomy and extraction to permit of efficient separation of the capsule is indicated by a recent experience. My patient, aged 65, had immature nuclear cataract. A capsulotomy according to Smith was done at 8 a. m. There was moderate gaping of the cut, with extrusion of a little gelatinous cortex. Eight hours later combined extraction was made. A large nucleus accompanied by much sticky cortex was with difficulty extracted. Immediately following the delivery of the lens vitreous appeared in the wound, so that contemplated irrigation had to be abandoned. The ultimate result was fair—vision 6/10.

DR. W. M. SWEET, Philadelphia: Although I have not performed many preliminary capsulotomies according to Dr. Smith's method, I have had an opportunity of noting the effect of the operation in the twenty-five or thirty cases operated on by Dr. H. F. Hansell. In the earlier cases either the Knapp or Ziegler knife-needle was employed, but later the special knife devised by Dr. Smith was used, made by Tieman. Owing to the somewhat faulty construction of the knife, the blade being much wider than the circumference of the shank, the aqueous escaped after the first incision in the capsule, so that the second cut was made with difficulty. In all the cases the extraction was done twenty-four hours following the capsulotomy, as it was difficult in the hospital cases to arrange to operate six hours later. I was especially impressed in these cases by the different behavior of the cataracts even when the incision in the capsule appeared to be of the same extent. In the majority there was only moderate increase in the opacity and in the swelling of the lens. In a few there was a decided reaction. Even with the preliminary capsulotomy, many of the cases showed retained cortex in the pupillary space that required the use of the irrigator. Whether we operate in unripe cataract by the Homer Smith procedure or by preliminary iridectomy, I believe that many cases of retained cortex in the pupil are the result of an inadequate incision at the time of the final extraction, the angles of an incision wiping off portions of the cortex and leaving it in the anterior chamber.

DR. F. C. TODD, Minneapolis: The operation has been generally accepted as a distinct advance in this class of cases. I cannot agree with Dr. Feingold that we should wait some days before proceeding with the extraction. It seems to me it is better to operate within a few hours than to wait for reaction. One point was brought to my attention by Colonel Elliot, who was enthusiastic as to the operation—the wisdom of operating in the morning instead of the afternoon as suggested by Dr. Smith, in that glaucoma might occur within the first few hours and there would be opportunity for extraction early during the daytime. I have, therefore, in more recent cases, operated in the morning and done the extraction in the afternoon. There is one more advantage in this operation that has not been mentioned. It is evident that one cannot always make a diagnosis of an immature cataract. I am sure others make this mistake. I have extracted not a few lenses that were entirely hard, that has been postponed because of supposed immaturity by other oculists. This operation enables us to diagnose the consistency of the lens, it is an "exploratory incision," and if we find we have made a mistake and the lens is hard we can extract at once after making the capsulotomy.

DR. M. BLACK, Denver: Is the knife made right?

DR. HOMER SMITH, Norwich, N. Y.: It is a great pity that those who make the instrument do not have to use it. The

blade should be beaten from the shank. The belly of the blade should be acutely sharp so that each portion will come in contact with the incision. If not acutely sharp you will lose vitreous. Each knife should be tested out on a drum to see that the cutting edge of the blade is sharp clear up to the point. On account of lack of this some accidents have occurred. Tiemann makes the best knife. Dr. Risley takes up the point of preliminary capsulotomy as a routine measure in acute cataracts. It is universally adopted in England. In my paper the matter of the immediate extraction of morgagnian cataract is taken up, and I do not allow the six-hour interval because there is no cortex to deal with. If there is loss of aqueous at the time of the capsulotomy there is no trouble following, because the anterior chamber can be refilled by an irrigator with normal salt solution and you can go on with the extraction immediately without further waiting. In all the cases reported, 180, there were no infections whatever, so that matter is a negligible factor. But high tension is another matter. In a number of cases there will be high tension, and the longer the interval between the preliminary capsulotomy and the extraction proper the greater the risks of high tension. The high tension cases require some variation in the technic. A speculum should not be used, but fixation. If the anterior chamber is shallow, then you have three operative courses: The incision can be begun by and continued with the scissors curved on the flat. If the anterior chamber is almost completely obliterated, the section can be made from the outside with a broad-bladed scalpel through the sclerocorneal junction. I have seen that done at Moorfields repeatedly. The scissors may be applied in that case also. In all high tension cases the section can be made full size in the ordinary way, but should be completed with the utmost gentleness on account of the risk to the vitreous. I said in my paper that secondary operations are rare; I did not say they are never required. There is a small percentage of cases in which it does not work.

ACTIVE IMMUNIZATION IN DIPHTHERIA AND TREATMENT BY TOXIN- ANTITOXIN*

WILLIAM H. PARK, M.D.

AND

A. ZINGHER, M.D.

Assisted by

M. H. SEROTA, M.D.

NEW YORK

The property of toxin-antitoxin mixtures to produce immunity in animals has long been known. One of us (W. H. P.) published a series of successful results in 1903. Smith suggested the attempt to immunize children, but no one undertook it until 1912, when von Behring made the attempt.

In May, 1913, Behring published the results obtained in human beings. The combined substances were either neutral or slightly toxic to the guinea-pig. Individuals were injected with small doses (from 1/20 to 1/10 c.c.) which were repeated in from seven to ten days. The first injections were made subcutaneously or intramuscularly, while later the intracutaneous administration was favored, since the more distinct local reaction was believed to induce a greater efficiency of vaccination.

The results as reported from different observers have not been uniform and as a rule are not distinctly stated. Hahn reports antitoxin production in thirty-

six out of forty treated; as we shall see later, the fact that twenty-five of the forty patients had natural antitoxin already present modifies greatly the favorable nature of this result. Failure to respond was at first attributed to a lowered general condition but now we realize that it was because the susceptibility to the immunizing response to vaccine varies. It seems greatest in young adults. Zangmeister reports the interesting fact that the new-born are nearly a hundred times less susceptible to vaccine than adults. Kleinschmidt and Viereck report the active immunization of twenty-seven cases, but give no definite data. They advise combined active and passive immunization in persons exposed to diphtheria and also suggest the use of the Schick reaction in determining antitoxin content of persons after vaccination. Kissling reports results at Hamburg-Eppendorf in the immunization of 310 patients who were exposed to infection. In the 111 who were injected twice, no diphtheria developed. In the 109 cases injected once, 8 patients developed clinical diphtheria. During an epidemic of diphtheria, Hahn and Sommer vaccinated part of the inhabitants of several villages: of 633 patients considered fully immunized only two developed mild diphtheria, but 10 of the group developed it during the first ten days. The disease continued to spread to some extent among those not vaccinated. Bauer finds that the persistence of the bacilli in carriers is not shortened by active immunization. He believes that not only all patients with antitoxin, but also those without natural antitoxin can be immunized, if sufficient doses and amounts of vaccine are injected.

The interval between the injections of vaccine and development of antitoxin varies in different cases. According to Hahn it is usually not less than three weeks. Kleinschmidt and Viereck found it shorter—even eight days. Patients with natural antitoxin usually show early and considerable antitoxin production. They also generally show a somewhat greater local susceptibility to vaccines. This according to von Behring is due to sensitization from previous infections with the Klebs-Loeffler bacillus.

According to von Behring, the higher temperature of fever will destroy antitoxin at an increased rate so that an amount of antitoxin, which generally protects, fails to do so in measles and scarlet fever. Schick and Karasawa find, however, that no change in antitoxin content is caused by measles. Von Behring considers that 0.01 unit per cubic centimeter is sufficient to protect healthy persons. Much less than this probably suffices except under unusual conditions, as in scarlet fever.

PERSONAL EXPERIENCE

During the past twelve months the attempt has been made to immunize actively against diphtheria the patients in the scarlet fever wards of the Willard Parker Hospital. Owing to the large number of diphtheria-carriers admitted, the conditions in this hospital during the winter were such that on the average about one-quarter of the inmates were diphtheria-carriers.

For this purpose mixtures of diphtheria toxin and antitoxin were prepared, either slightly antitoxic, neutral or slightly toxic to the guinea-pig. A strong diphtheria toxin was used, where the minimum lethal dose was 0.0023 c.c. and L+ dose 0.27 c.c. The mixtures represented B 50 per cent., A 66 per cent., G 66 per cent., F 80 per cent. and E 90 per cent. L+ toxin to each unit of antitoxin. The L+ dose of toxin is

* From the Research Laboratory of the Department of Health.

the amount which, when mixed with 1 unit of antitoxin and injected into a 250-gm. guinea-pig, will cause its death at the end of four days. One c.c. of Mixture E caused when injected into a guinea-pig at first a slight local induration and then in about twenty-days paralysis.

The injections were made subcutaneously or intramuscularly in doses of from 0.25 to 1 c.c. of undiluted vaccine; a few of the non-immune persons received as high as from 3 to 5 c.c. at each injection. The dose was repeated two or three times at intervals of from three to seven days. The injections were made posteriorly in the intrascapular region, in some over the insertion of the deltoid.

The local reactions consisted as a rule of varying degrees of redness, induration, pain and tenderness; in part they seemed to depend on the size of the dose and in part on the individual susceptibility. Persons with natural antitoxin gave somewhat more frequently the stronger local reactions. The constitutional symptoms were as a rule rather mild; occasional temperature reactions of from 1 to 3 degrees were noted after larger doses of Mixture E.

The results of the active immunization were controlled by determining the antitoxin content before the injection; again three weeks and more after the injections similar examinations were made. The antitoxin content of the serums was estimated by Römer's intracutaneous method on the guinea-pig. As it was not possible to detect less than 1.160 unit in 1 c.c. of serum, anything less than that was considered as absence of antitoxin, although naturally some serums not showing this amount may have had a slight trace.

A group of 68 patients was injected with the various vaccines; of these, 44 had, before the injections, sufficient natural antitoxin to protect them against diphtheria. They all showed a decided production of antitoxin in a relatively short time (in some as early as seven days). The remaining 24 patients had no appreciable antitoxin before the injections; of these, 6 gave rise to distinct antitoxin production while 18 failed to respond.

Five patients of the 18 which did not respond developed slight or moderate clinical diphtheria two weeks or more after the first injection. Four had tonsillar exudates and one nasal diphtheria with visible membrane in the anterior nares. Cultures were positive, and the isolated Klebs-Loeffler organizations virulent.

We thus found that persons with natural antitoxin gave a ready response to active immunization, while those with no appreciable natural antitoxin failed to do so in a considerable proportion of cases. A larger group of susceptible patients was, therefore, selected to determine these results in a greater number of cases. For this purpose the intracutaneous reaction of Schick with diluted diphtheria toxin was used. This reaction depends on the local irritant action of toxin in the absence of antitoxin. A dilution of diphtheria toxin is made of such strength that 0.1 c.c. contains 1/50 minimum lethal dose for the guinea-pig. This amount is injected intracutaneously on the flexor surface of the forearm. A positive reaction appears in from twenty-four to forty-eight hours, and is characterized by a circumscribed area of redness and slight infiltration, which remains for from seven to ten days. After fading, a brownish pigmented area is left for days and weeks which in beginning generally shows superficial scaling. According to Schick, a positive reaction indicates that there is less than 1/30 unit of

antitoxin in 1 c.c. of blood. The majority have none at all. Such persons he considers susceptible to diphtheria. Our estimations agree with his conclusion.

The Schick reaction was again employed three weeks and more after the vaccination to indicate clinically whether or not the patients had responded to the immunization. In many, bleedings were taken and tested in addition before and after the injections.

Ninety persons without appreciable antitoxin were thus selected who received full immunizing doses of Vaccines E and F; of these only twenty, or 22 per cent., gave rise to a decided production of antitoxin (1/20 up to 10 units per cubic centimeter). Among the remaining seventy patients a considerable number were found in whom the Schick reaction was fainter, but not obliterated when the tests were made four or five weeks after the injections; the antitoxin produced, however, was too small in amount to be detected in the animal test. Seventeen of the seventy patients who failed to respond developed clinical diphtheria twelve days or more after the first injection of the vaccine; those who showed symptoms before twelve days were not included in the group. Twelve patients had purulent nasal discharges sometimes tinged with blood, four tonsillar exudate, and one laryngeal diphtheria. The cultures were positive, and the isolated organisms virulent.

We note that active immunization in this group of susceptible persons gave rise to decided antitoxin production in 22 per cent. of cases; the interval between vaccination and development of immunity was generally long, as a rule not less than two weeks. Under conditions of exposure about 20 per cent. of those who failed to respond have developed clinical diphtheria.

SUMMARY

Active immunization produced a very decided increase of antitoxin in a relatively short time in all persons who had natural antitoxin. These, however, were immune to diphtheria before the injections were made.

In a series of 700 scarlet fever patients of varying ages tested by us for natural immunity by the Schick reaction, 400 gave a negative reaction. Fifty-seven per cent. were, therefore, naturally protected and needed neither active nor passive immunization. Less than one quarter of the remaining 43 per cent., which were probably susceptible to diphtheria, reacted to active immunization with mixtures of diphtheria toxin and antitoxin to a degree sufficient to immunize them surely. A larger percentage developed a trace of antitoxin which was possibly enough to give a slight protection.

CONCLUSIONS

Those who are definitely exposed to infection should be passively immunized even if the toxin-antitoxin injections have been given.

The use of the Schick test will eliminate the necessity of immunizing about two-thirds of those subjected to exposure, as judging from a year's experience, those not reacting are immune.

Those found to be naturally immune probably continue immune for a considerable period of time, possibly indefinitely.

Active immunization is indicated when there is no immediate danger of infection and when it is desirable to lessen the number of susceptible persons. It is too early to decide whether active immunization should be

attempted on a large scale. The lack of a sufficient response of at least 50 per cent. of those susceptible to diphtheria and the fact that the immunity lasts for but one or two years are drawbacks that will probably limit to some degree its usefulness.

THE USE OF ANTITOXIN IN DIPHTHERIA *

SAMUEL S. WOODY, M.D.

Chief Resident Physician to the Philadelphia Hospital for Contagious Diseases, Department of Public Health

PHILADELPHIA

Conclusions as to the use of any remedy in a disease must be based, in the final analysis, on practical experience. Theory may aid us in finding the remedy and may guide us in its use, but our final judgment must be based on results alone.

Diphtheria antitoxin has been abundantly proved to be a specific for diphtheria, and a cure when used in correct doses at the proper time. With an agent at our service, known for such a length of time, of such acknowledged usefulness, and of such direct and specific action, it is surprising that there should exist even that small percentage of failures which we must constantly face. It is true that the circumstances of general practice and the possibilities of error in diagnosis offer limitations to the immediate and proper use of the serum which make the attainment of ideal results out of the question. Nevertheless, it must be apparent that it should be possible still further to reduce our mortality, reduce it to a much smaller figure than it is at present. If, therefore this result is to be achieved, we must accomplish it by a change in the method of our use of the specific for the disease—general hygiene of the patient and medication being watched always in addition.

This paper is based on personal observation of over ten thousand cases of diphtheria at the Philadelphia Hospital for Contagious Diseases. This series of cases has given me ample opportunity to observe the action of various doses of antitoxin.

The use of antitoxin in diphtheria is so eminently successful because diphtheria is primarily a local disease, exerting its harmful effects through the formation of a toxin by the organism causing the diphtheritic process. This toxin is quickly spread throughout the entire body and attacks early the nervous system, heart and kidneys, all structures of vital importance. The resistance of the body to this toxin is by the formation within of an antitoxin, and this protective action we aid by the introduction from without of an antitoxic serum.

The term "antitoxin" as used in this paper refers to the serum containing antitoxin—the diphtheria antitoxin of the United States Pharmacopeia, officially defined as "blood-serum from horses immunized against diphtheria poison." There is also in use a method for determining the amount of antitoxin in the immune serum. This method, by which the content is expressed in certain definite units, enables us to measure comparatively our doses and in this way is of great aid. But there has been devised no way of

estimating the number of such units needed by a particular person suffering from diphtheria. This we can determine empirically only—not entirely by any particular symptom in a given case, but by the observation of a great number of similar cases.

Of course our dose must be determined to a great extent by the size and susceptibility of the patient, the severity and extent of the lesions, the length of time the patient has been ill and perhaps by the virulence of the disease in a particular epidemic.

I am entirely satisfied that diphtheria antitoxin as generally used is given in doses far too small. Our object should be to accomplish by its use the neutralization of all the diphtheria toxin within the body and the giving of a certain excess of antitoxin for the further use of the body in counteracting fresh toxins that may be formed at the focus of infection.

A discussion of the advisability of using larger doses of diphtheria antitoxin must cover three points:

1. Our objects in giving larger doses.
2. The benefits to be derived from such doses.
3. Possible objections to their use.

The object we have in view is the rapid and complete neutralization of the diphtheria toxin by a single dose of antitoxin, if this be possible. Most cases of diphtheria treated by present methods are given numerous doses of serum—small in comparison with those which may be used safely. In a good percentage of cases the patients recover—when finally the toxins have been balanced by repeated masses of antitoxin in addition to the antitoxin elaborated within the body. Why not make the endeavor to give at once as an initial dose such an amount of antitoxin that this neutralization will be accomplished without delay, and that possibly there will be an excess of antitoxin still in the system to combat toxins later elaborated. To give a dose too small invites disaster by causing delay in checking the disease process. To give too large a dose can do no harm and may be a safeguard for the future.

The benefits derived from so-called large doses through the rapid neutralization of toxins are three-fold:

1. The patient is rapidly cured of the disease.
2. Complications are minimized.
3. The patient's recovery is hastened and the infectious period shortened.

The rapid action of even moderate doses of antitoxin is often marvelous. Far more certain, rapid and permanent are the effects of large doses. By overwhelming the toxins, recrudescences are rendered less liable to occur. Complications, with few exceptions, result directly from the action of the toxins on the vital structures—the heart, kidneys and nervous system. It must be evident at once that if we rapidly neutralize the toxins and avoid the formation of new toxins or forestall their effects, we must be lessening the probability of the occurrence of complications.

Before proceeding to a discussion of the possible harmful effects of large doses, two points should be carefully noted:

A. The location of the disease process and its extent, the virulence of the infection, the patient's general condition and the duration of the illness must all be considered in arriving at a conclusion as to what a correct dose of antitoxin is in every particular instance.

* Read before the Section on Pharmacology and Therapeutics at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

B. The following indicates just what I mean by large doses, and what doses I am accustomed to give.

No case of diphtheria, however mild, should receive less than 10,000 units.

Both tonsils well covered with exudate, of one or two days' duration, from 30,000 to 60,000 units.

Both tonsils well covered with exudate, with palate, uvula and nose involved, of three days' duration or thereafter, from 150,000 to 300,000 units.

Nasal cases, simple, 20,000 units.

Nasal cases, with marked symptoms of toxemia, from 50,000 to 150,000 units.

Laryngeal cases, from 30,000 to 45,000 units.

Laryngeal, in combination with other varieties, should mean a corresponding increase in dosage.

The theoretical advantages of large doses have been stated. One practical advantage also is the avoidance of the pain and discomfort of frequently repeated doses. What are the objections which might be urged against the use of large doses?

1. Such an amount of antitoxin might prove harmful to the patient. This is disproved by actual experience. Untoward results from the use of diphtheria antitoxin have followed the use of moderate or even small doses just as often as after the use of large ones. Indeed, it has been shown that such a result is not due to the antitoxic bodies themselves, but to the serum alone. There is then a great possibility that such after-effects might be avoided entirely, certainly minimized, by the higher concentration of the antitoxin.

2. The possibility of anaphylactic shock. In my experience this is extremely rare. Its occurrence is of such great rarity that it cannot be allowed to influence us in the least. Too many lives are lost by too little antitoxin being given to allow a theoretical possibility to keep us from making a cure.

Local sloughing from the bulk of the serum is very rare and will be avoided entirely by further concentration.

My actual results show well in the accompanying table.

RESULTS IN AUTHOR'S CASES

Year	No. of Cases	Deaths	Per Cent.	Dosage
1908	1,426	127	8.55	Very small.
1909	2,153	144	6.69	First year large doses were used.
1910	1,870	120	6.42	Larger doses about as used in 1909.
1911	1,895	130	6.86	Doses smaller than in 1909 and 1910.
1912	1,676	101	6.02	Larger doses used.

The advantages of large doses are really greater than would appear from these statistics, which include deaths from all types of diphtheria.

The benefits to be derived from large doses are less apparent in the treatment of laryngeal diphtheria than in any other form of the disease. This is due to the fact that practically all cases of this variety are sent to the hospital only when far advanced and because the condition then to be combated is not a toxemia, but rather a physical one, due to the location of the membrane. We have to deal with principally a mechanical obstruction to the intake of air resulting in insufficient oxygenation. These deaths are due to asphyxia and exhaustion or to bronchopneumonia, and not to the toxemia of diphtheria.

In our tables this number of laryngeal cases always influences the death-rate. Were we able to show the results of large doses of antitoxin when the toxemia alone must be dealt with, our figures would be even more favorable.

In the septic types, aside from the great satisfaction of feeling that the doubt as to the ultimate outcome has been set aside, we have also the comforting knowledge that by the use of large doses of this specific we have brought to a minimum the chances for the development of that most dreaded of all complications, postdiphtheritic paralysis.

The occurrence of serum sickness and serum rashes is not a bar to the use of large doses. The rashes, however, are frequent, having occurred in 43.4 per cent. of 1,000 carefully analyzed cases.

Of these, 0.3 per cent. were scarlatiniform, and 1 per cent. morbilliform. In 11.2 per cent. no variety was stated, and in 30.9 per cent. the rash was urticarial. The appearance of the rash was as early as a few hours and as late as several weeks. I have never observed dangerous or alarming serum sickness, though a few of the patients have become painfully ill and remained so for as long as a week.

Since, then, there is no bar to the use of large doses, there remains but a summary of my results with their use.

These results are:

1. Prompter local cure.
2. Quicker improvement in the patient's general condition.
3. Permanence of curative action.
4. Avoidance of complications.
5. Reduction of mortality.
6. Harmlessness of large doses.

I doubt, indeed, whether we have as yet used diphtheria antitoxin in doses that give its full therapeutic efficiency.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. WILLIAM H. PARK AND SAMUEL S. WOODY

DR. LEWELLYS F. BARKER, Baltimore: While it is desirable to use enough antitoxin, it has not, in my experience, been necessary to use as large doses as Dr. Park has recommended. I should like to ask Dr. Park if he has seen diphtheria develop in a patient in whom the Schick reaction had been found to be negative? This reaction seems to me very important. Every physician in the country should know about it at once, so that the benefits of this discovery may be widely disseminated.

DR. JOHN F. ANDERSON, Washington, D. C.: Dr. Park's first statements in his summary, that those who are exposed to infection should be immunized, should be emphasized. We have been somewhat scared by anaphylaxis. I believe that anaphylactic reactions from a second injection are very rare and they need not be given much practical consideration. In diphtheria the time of injection is important. Ten thousand units is of more value when given early than 100,000 or 200,000 when given later. I believe that we usually get a full effect without the large doses of 100,000 or 200,000 units of antitoxin.

DR. J. J. KINYOUN, Washington, D. C.: Some years ago we had a number of horses which were not producing the amount of antitoxin they should and we transferred them. They were kept without immunization for four months and then used for other antisera. In two of these horses, tested four years afterward, not having had any antitoxin during this time, the blood showed 16 units per cubic centimeter of antitoxin. The active immunization of these horses would seem to be of long duration. A careful estimate made of the cost per thousand units, just after the precipitating method was introduced, showed that it ran from 6½ to 8¼ cents.

DR. P. S. ROY, Washington, D. C.: If we use larger doses of antitoxin we must reduce the price. According to Dr. Kinyoun a \$5 package costs the manufacturer 37 cents, and

if this is true then we should demand 10,000 or 15,000 units for the price we are now paying for 4,000 units.

DR. GUY L. KIEFER, Detroit: My results are based on a smaller series of cases than Dr. Woody's, some 882 cases since January, 1913. In the first six months of the treatment of these cases the minimum dose was 5,000 units; 5,000 to 10,000 units were given as an initial dose; beginning last July 10,000 units. The mortality rate up to July 1 was 8.24 per cent., and from July 1, 1913, to May 1, 1914, the death-rate was 4.1 per cent. I wish to emphasize early administration. We had no deaths in patients who received the antitoxin on or before the third day. With regard to the kind of case, the comparison between the smaller dose and the larger dose was on cases of approximately the same type.

DR. D. L. RICHARDSON, Providence, R. I.: We should give large doses early. I think that Schick's test would be of more value for the community than in an institution. In institutions the patients are more under control and diphtheria carriers can be separated. Relative to treatment, certainly, large doses should be given. In mild cases, of course, it is not necessary. I had one experience, however, which would need some explanation and in which antitoxin seemed to have a limited value. This was in a nurse who was all right at breakfast time. At noon she had two or three patches. At 5 p. m. cultures were found positive and antitoxin was administered. In all she received 150,000 units of antitoxin. In three or four days she was very ill with virulent diphtheria with edema of the neck, and later cardiac complications, etc. This case was seen early and if not so seen would no doubt have terminated fatally. With reference to early administration, we should obtain for the community what is possible in the hospital. In Boston City Hospital for fifteen years there have been many cases of diphtheria in nurses and doctors without any deaths, and if this can be done in hospitals it should be aimed at in the community.

DR. W. W. TOMPKINS, Charleston, W. Va.: How long after diphtheria has been in a house would Dr. Park lift the quarantine? If the persons in the house were given an immunizing dose, could they go out earlier than those who had not taken the immunizing dose, and are the latter a source of infection? Does Dr. Park advise the large doses sometimes given in diphtheria? Are they safe or necessary?

DR. SAMUEL S. WOODY, Philadelphia: Concerning the time of administering antitoxin, as mentioned by Dr. Anderson, it goes without saying that were we to administer the specific on the first day of the disease, and in a dose of 10,000 units, there would be no further need of antitoxin; furthermore, there would be practically no mortality. All experience bears us out in this statement. I stated in the beginning that my paper was based on personal observation alone. I have tried antitoxin in all-sized doses and in all types of the disease, and am firm in my belief that to obtain the best results we must give the serum in massive doses.

DR. WILLIAM H. PARK, New York: The Schick injection is given with a small hypodermatic syringe with a platinum point and 1/10 c.c. is injected into the skin. A raised whitish spot will be seen over the injection. It covers an area the size of a half-dollar. The injection must go into the skin and not subcutaneously, and the little raised whitish elevation must be obtained. In twenty-four hours it becomes bluish with a slight edema, passes off in forty-eight hours and gradually disappears, but leaves a pigmentation. A false reaction may be found and then a second injection must be given; this is due to the broth and probably happens in only 2 or 3 per cent. of cases. It is perfectly correct to use for four or five weeks. With regard to quarantine—the use of antitoxin does not affect the carrier at all. Carriers need not be prevented from going out. We insist on two negative cultures from the patient before the quarantine is lifted. With regard to Dr. Barker's question: No patient has developed diphtheria after a negative Schick reaction so far as I know. We feel absolutely safe in leaving a case with a negative Schick without immunization. Unquestionably, a patient may receive any amount and in twenty-four hours may develop malignant

diphtheria because the process has started, but after two or three days I have found such cases to be usually of syphilis or angina or something else. Dr. Woody stated that we cannot determine by experimentation how much antitoxin is needed in a given case. We try to give enough to neutralize the toxin in the body. We give the antitoxin in amounts large enough to get it from the tissues to the blood and out again to the local tissues where the toxin is generated; it is, therefore, the speed in getting to these various points which counts. It will be found that one-half of the patients have no toxin in the blood whatever. In the local cases a greater amount will be noted so far as the tissues are concerned. I agree with Dr. Woody that only a single dose of antitoxin is required, 5,000 units in mild, 10,000 in severe and 20,000 in malignant cases. So far as the appearance of the patient goes, the single dose has given better results, and so far as the mortality goes also. Mortality has dropped, probably owing to the single large dose. The antitoxin requires two days for 1/3 to be absorbed and another two days for the other 1/3 to be absorbed, so that it seems impossible that any larger amount will do any good. After twelve hours there is little toxin in the body except possibly locally in the tissues. We have kept to the single dose for the last year and we do this by taking a blood-test before the second injection. Ten thousand units intravenously is worth 100,000 units subcutaneously. We have in every way tested this and we find that larger doses than from 5,000 to 25,000 units make no difference. In the more toxic cases better results are obtained from the intravenous injection, but not so in the others. Forty thousand units will save any patient that 1,000,000 will. I have seen or heard reports of severe shock in a few cases in which large doses have been given, which the small doses would not have caused, but I agree with Dr. Woody that these are few. We have never had a death in our hospital from an injection of serum. I rather feel that a large primary injection coming through safely insures against fatal result from any other injection.

TREATMENT OF UNLOCALIZED INTRACRANIAL INJURIES BY DRAINAGE THROUGH A SUBTEMPORAL APPROACH*

V. P. BLAIR, A.M., M.D.

ST. LOUIS

The emergency service in the City Hospital of St. Louis gives, I believe, exceptional opportunities for the study of intracranial injuries. In the two years, 1910 and 1912 during which I was on the Visiting-Staff, I devoted my spare time to a study of them.

Of course, all cases presenting external or neurologic signs of localized head injury, that can be directly approached, are treated accordingly, but a great many suggest no special point of surgical attack, mostly cases in which the injury is at the base of the brain; these are usually generalized as fractures of the base of the skull. In very few of these is a fracture, if present, the most important lesion, the immediately grave symptoms arising from a concussion injury of the brain and its coverings.

A composite picture of such cases might be presented as follows:

The patient is unconscious or semiconscious, pulse slow, normal or rapid, respiration sometimes stertorous and with more or less disturbance of the reflexes and voluntary movements. The pupillary reflex is the one most frequently disturbed. There may or may not be bleeding from the nose, mouth or ears. Death may follow quickly or recovery may take place. In

* Read before the Section on Surgery, General and Abdominal, at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

a running series of eighty patients not operated on it was found that 20 per cent. died in less than two hours and over 50 per cent. in the first twenty-four hours. Of the patients that survived twenty-four hours, about half lingered for several days, being restless and semiconscious; later the pulse became weak and rapid, followed by coma, very high temperature and death.

At necropsy I have never seen a bony depression that could directly account for death, but there is intradural extravasation of blood, thrombosis of some of the cerebral veins with localized softening of the brain; these changes are most marked above the tentorium. In few of these cases there is interventricular hemorrhage or evidence of deep extensive primary brain injury, for such patients die more quickly. There is, however, not infrequently actual pulpefaction of the under surfaces of the frontal and temporo-sphenoidal lobes. These necropsy findings are concurred with by Dr. D. L. Harris, who was for six years pathologist of the City Hospital. The general picture of the late fatalities is the one to suggest that death was due to some secondary circulatory change rather than to the primary injury. This has been designated as an encephalitis, but in very few cases is there evidence that there had been an infection.

It is characteristic of all soft tissues, after injury, to become swollen, because of an increased blood-supply and other changes which follow and which seem to be, at least in part, related to repair.

The brain is enclosed in an unyielding case which does not provide for an increase in bulk, and further, there is frequently an extravasation of blood that actually lessens its normal space. On the theory that the subsequent clinical symptoms and necropsy findings might in part be due to a lack of space and a consequent interference with circulation, a means was sought to correct this. Repeated lumbar punctures were tried but, though this brought about a clear spinal fluid, the results were not satisfactory.

It seemed to me that single or bilateral subtemporal decompression and drainage of the subdural space should be helpful for the following reasons:

The operation is easily and quickly performed, leaving the defect in the least exposed position and protected by the temporal muscle. With the finger in this opening a large part of the orbital surface of the frontal lobe, the under surface of the temporal lobe and a fair part of the convexity of the hemisphere and inner surface of the skull can be explored; clots and also pulped parts of the under surfaces of the temporal and frontal lobes can be withdrawn so that the drainage prevents a further accumulation of blood and rapidly clears the cerebrospinal fluid.

If a disinfectant such as hexamethylenetetramin is used, the drainage of the cerebrospinal fluid insures the dissemination of the disinfectant throughout the subarachnoid spaces.

Finally, the presence of the decompression defect allows for a certain amount of expansion of brain, insuring a freer circulation and possibly accommodation to a hidden clot.

With the help of Dr. A. H. Ryan an effort was made to substantiate or disprove those suppositions by animal experimentation in the physiologic laboratory of the Washington University, with not very conclusive results. These experiments were unsatisfactory for the following reasons:

The concussion injuries of the brain with which we were dealing are dependent on the size of the human

brain and the elasticity of the human skull, which is not to be duplicated in any available animal. As a result it is very difficult to administer a concussion injury from which the animal cannot be revived without operation and which, on the other hand, will not be immediately fatal. We used young kittens that have a comparatively thin calvarium; and in dogs we undertook to overcome the skull resistance by freeing an osteoplastic flap in the vertex and after suturing the scalp allowing the wound to heal entirely before applying the injury blow. A machine, fashioned somewhat after a pile-driver, was contrived that would deliver a blow of measured force. The weight was so controlled that it could travel only a measured distance, varying between 2 and 5 mm., after touching the skull. In some cases the blow was applied to the temporal region without previous osteoplastic operation. In all cases a knock-out blow was given; in some cases the animal died immediately and in most instances artificial respiration was required for a time after the blow. All animals were etherized for the preliminary operation. Animals that showed nervousness were etherized before striking the blow. The machine acted with the greatest precision and the animals that were knocked out without previous etherization suffered no more pain than a felled ox.

In about half the animals that survived long enough, an immediate subtemporal opening was made in the skull and dura, this area having been previously shaved and cleaned. The making of the opening required about three minutes.

The points established at operation were, that an animal struck on the vertex, under the proper circumstances, showed at necropsy a basal clot around the cisterna magna and the interpeduncular space and enveloping the pons and medulla. In animals struck in the same way but on which an immediate subtemporal decompression was done, such a clot was either absent at necropsy or at least absent on the side that was drained.

In some animals the blow was applied low down over the temporal region without previous osteoplastic operation. In one of these it was demonstrated that a dog which had an apparently lethal injury, unconscious, requiring artificial respiration, almost totally paralyzed and with a deep and extensive depressed fracture, in which an immediate subtemporal decompression and drainage was done on the opposite side to the injury, could gradually improve until in ten days almost all paralysis had disappeared. For six days this dog had to be fed with a stomach-tube. We have extensive operative and hospital notes on thirty-seven of these animal experiments.

In the City Hospital we found records of forty-two cases in which a single or bilateral subtemporal operation was done in my service for severe unlocalized intracranial injury, during the two years specified. These operations were done by the residents, Drs. Sewing, Hewitt and Hagler, but the majority by myself. During this period the operation was not done indiscriminately but, it being to us a new procedure, it was done, with few exceptions, only in cases of apparently very severe injury. Lumbar puncture was used to determine the presence of free intradural hemorrhage. Of these injuries, five were deep gunshot wounds of the brain.

Besides the behavior of certain individual cases, the most striking observation in this series is that out of

forty-two cases in which the injury could not be located before operation, in thirty-one, through a single or bilateral subtemporal operation, pulped brain substance, a subdural clot or severe hemorrhage was found and dealt with. In seven others, either an extradural clot or contused brain was exposed.

On account of the diminutive size of this series of operative cases, no statistical conclusions of real value can be drawn, but as a matter of interest I have lately made certain comparisons, between the results in this series, with a running series of eighty basal injuries not operated on in another service. In these eighty cases without operation, there were seventeen deaths within two hours after admittance and for the sake of comparison, these were eliminated, leaving sixty-three injuries not operated on in which there was survival for two hours or more. In the series with operation, seventeen patients were operated on within two hours after the patient was received. The proportion of very early operations would have been much higher if, in the early part of the series, we had not waited to see how the doubtful cases would do without operation. In the latter part of the series, the majority of patients were operated on within two hours after admittance.

In the series of sixty-three patients not operated on who lived more than two hours, 35 per cent. survived.

Of the forty-two patients operated on, 57 per cent. survived.

The time of operation would appear to be important. In half of the successful cases, but in only one-third of the fatal cases, the operation had been done within two hours. Of the patients on whom operation was performed within two hours (and this means that the dura was open within the two hours) 70 per cent. survived. It has already been stated that in sixty-three patients not operated on surviving two hours or more, only 35 per cent. lived.

The significance of time as a factor in prognosis is indicated by the following data:

Of those not operated on who survived twenty-four hours, 58 per cent. ultimately recovered.

Of those operated on who survived twenty-four hours, 75 per cent. recovered.

Of those who survived forty-eight hours, about 75 per cent. in either series ultimately recovered.

Next to disturbance of the sensorium, the most constant single sign of severe brain injury was disturbance of the pupillary reflex. Of patients giving this sign in the series without operation, 27 per cent. recovered; in the series with operation, 57 per cent. recovered.

This comparison between the two series of cases is not presented with the idea of proving a point, but simply as data that are interesting as far as they go. These figures were only lately compiled, but two years ago after watching the operated series here presented, I concluded to open every skull subtemporally of every patient seen early with supposed unlocalized brain injury, and have done this ever since and believe it is a good procedure. The opening of the cerebellar fossa is relatively difficult and shock-producing, and as in most cases the injury is above the tentorium, I have not used this route.

In practice several points have been developed that had not been thought of when the plan was made.

In the presence of an open fracture of the vertex, when on exposing the dura it is demonstrated that the latter has not been punctured but that there is a subdural clot, the latter can be partially removed and

drained through a subtemporal opening with less risk of brain infection or of injury to edematous cortex than if the dura is incised at the site of the original injury. We have done this with satisfactory results several times. Further, if the middle meningeal artery is suspected as being the source of hemorrhage, which is comparatively seldom the case, this vessel can be controlled from the subtemporal wound.

The technic of this operation is simple. A fair area of the temple is shaved and iodine is applied. A curved incision, convexity downward, is made from the pterion to behind the upper attachment of the ear, through the skin and temporal fascia. The temporal artery is caught and the flaps forcefully retracted with hooked retractors. The fibers of the temporal muscle are separated with an elevator and these are drawn apart by retractors held by another assistant. The skull is opened to the size of a half-dollar, the dura incised in several directions, the posterior branch of the meningeal artery being tied or caught with a Cushing clip. The neighboring surfaces of the brain are gently explored, and clots hooked out with the finger. A piece of rubber glove drain is inserted in the direction of the clot and the muscle and skin-flaps are closed. The drain is removed in twenty-four hours. In severe cases, in injuries in which there is evidence of intracranial pressure but no clot found, or when the respiration is disturbed by the operation, it is repeated on the other side. The operation is usually done on the right side first. If after drainage ceases at the wound, there is any evidence of pressure, repeated lumbar punctures are done. If carefully and gently done, I do not believe that the operation described is ever likely to cause real damage. It may hasten death by a few hours or minutes, in a patient who has a rupture of one of the large cerebral arteries, but such a patient would be unconscious and already doomed.

Metropolitan Building.

ABSTRACT OF DISCUSSION

DR. CHARLES A. ELSBERG, New York: I agree with Dr. Blair concerning the importance and the value of subtemporal decompression in fractures of the skull with brain injury, with hemorrhage under or outside of the dura in a large number but not all of the patients. One has to individualize, and to watch each patient; only those patients who show either very marked symptoms from the beginning or who show steadily advancing symptoms require operative interference. A sign of value in this respect is the change in the eyegrounds. One can almost foretell the symptoms of pressure that will appear from the changes in the retinal vessels. When the symptoms are very marked or if the symptoms are steadily progressive, decompression on one or both sides with or without opening of the dura and with or without incision of the cortex is required. One point which has been to me, at least, of the utmost value in doubtful cases is puncture of the skull. We know very well that in not a few of these patients with fractures of the skull the symptoms are due, not to the gross hemorrhage in or around the brain or outside the dura, but to numerous small hemorrhages throughout the brain substance. It is this condition which used to be called cerebral shock. Conditions of this kind often give the symptoms of a gross hemorrhage on the surface of the brain; to differentiate between the cases in which there is a gross injury (in which a subtemporal decompression with removal of the clot is indicated) from those with multiple hemorrhages (where operation is not indicated, except for a secondary edema), puncture of the skull is most useful. To illustrate: if the introduction of the needle through a small skull-opening down to the dura is

negative, push the needle through the dura and aspirate again. In this way one can differentiate between the cases which need operation and those which do not. There is nothing more disappointing than to open a patient's skull for symptoms and find no marked increase of pressure and realize that you have to deal with a case of multiple hemorrhages in which operation would have been better avoided.

DR. C. A. EVANS, Milwaukee, Wis.: It is apparent that this operation has not met with general acceptance. In order to determine whether or not it is worthy of acceptance I believe it is worth while to report the results obtained. I have operated on twenty-five cases by this method. Most of these were cases of basal fracture, in which the injury itself did not afford sufficient relief from pressure, and lumbar puncture showed bloody fluid. There was a mortality of 20 per cent. Taking the average mortality following such injuries without operation as 50 per cent., this is a reduction in mortality of 30 per cent., approximately what Cushing claims for the operation. The saving of life, however, is not the only consideration, for we must guard against the remote possibilities of the injury. In skull injuries with compound or depressed fractures or when a piece of bone has been removed either by the injury itself or by operation, there is less chance of subsequent trouble than there is in the so-called closed skull fractures. If this is true then surely an opening beneath the temporal muscle, over a mute area of the brain, should lessen the danger of cerebral complications. In two of the cases there was an extradural hemorrhage, and this approach permitted the ligation of the main trunk of the middle meningeal artery and the removal of the clot. I believe that this is the approach of choice in middle meningeal hemorrhage. In two of the cases a primary bilateral drainage was done. Three showed no improvement after unilateral drainage and a later drainage was done on the opposite side with recovery. I do not believe a decompression alone is sufficient. The brain should be elevated and a drain placed in the middle fossa. The whole question of intracranial injuries is one of intracranial pressure. The operation is not one for the open treatment of skull fractures but for the open treatment of intracranial pressure. It matters not what this pressure is due to or whether or not there is a fracture. The important thing is the amount of the pressure and the ability of the brain to withstand it. Trauma to the brain, like trauma to any other part of the body, is followed by the processes of reaction, which is a space-restricting process. Subtemporal drainage relieves this space restriction, absorption takes place, and the circulation is given its best chance to return to normal. There is a large percentage of intracranial injuries that are primarily fatal and the mortality cannot be reduced. Some patients will recover whether operated on or not, either because of the non-severity of the injury, or because of relief from pressure afforded by the injury itself or by lumbar puncture repeated as needed; a large percentage will recover only after a basal drainage, some after unilateral, others only after bilateral drainage.

DR. C. E. RUTH, Des Moines, Iowa: In 1889 I reported a case of injury to the skull in which a clot formed beneath the dura and the skull in a child who fell 15 feet and struck on its head on a plank sidewalk. He was trephined and the clot beneath the dura and one beneath the skull and external to the dura were found. The child recovered, and in reporting the case I said we can expect this to occur only in young children in whom the elasticity of the skull is such that after having been driven against the soft brain it will spring away and tear the branches of the middle meningeal artery loose. Immediately after this Dr. J. McFadden Gaston of Atlanta, Ga., wrote me that he had a case in a man aged 56, the symptoms disappearing under purgation, without operation, and the patient died from disturbances of a large clot that formed in the middle fossa extending from the base to the vertex, disproving my theory with regard to the liability of fracture. In another case which occurred in my experience, which was immediately fatal, a clot as large as my hand extended from the base to the vertex of the

skull over nearly the entire skull on one side with absolutely no sign of checking of the skull showing at any point. I wish simply to emphasize the importance of what Dr. Blair has said in his paper with reference to the possibilities of relief from the use of the decompression operation. I take exception to decompression without opening the dura. I can conceive of no such thing being possible except it be in a case in which the blood is extradural. To do a decompression operation it is imperative that we open the dura.

DR. VILRAY P. BLAIR, St. Louis: Dr. Elsberg did not mean to make that statement about not opening the dura. These operative cases were of the most severe type. In almost all of them that was determined by lumbar puncture and by getting free hemorrhage along with the symptoms. Further than this, we became convinced that the chance of saving patients decreased with every hour that the operation was put off. Finally, I believe when one has a brain injury without gross hemorrhage the patient may possibly be helped by a decompression, thus giving a freer circulation.

THE TREATMENT OF TABETIC OPTIC ATROPHY WITH INTRASPINAL INJECTIONS OF SALVARSANIZED SERUM

A PRELIMINARY REPORT

GEORGE T. JOHNSON, M.D., L. Z. BREAKS, M.D.

AND

AUGUST F. KNOEFEL, M.D.

TERRE HAUTE, IND.

While one would expect salvarsanized serum to exert about the same influence on the optic atrophy as on the spinal involvement in tabes dorsalis, we deem the observations made in two cases of tabes with optic atrophy treated by intraspinal injections of salvarsanized serum to be of sufficient interest to warrant reporting them. One was a well-marked case of tabes with optic atrophy; the other showed little outside of the ocular findings.

The technic of Swift and Ellis was followed, as described by Hough¹ and McCaskey.² At first the blood was allowed to stand over night to separate the serum, but later separation was effected by centrifugalization and the whole operation completed at one time. The neosalvarsan was dissolved in about 10 c.c. of reesterilized freshly distilled water in a glass syringe, and the blood was aspirated under 40 mm. negative pressure into a 2-ounce skimmed milk bottle of a Babcock tester, so that there was comparatively little exposure of either to the air. All injections were made in the office.

CASE 1.—W. T. C., man, aged 35, married, no children, lineman, with negative family history, had measles when 7 years old, and eruption without sore throat ten years ago, diagnosed as measles. He knows of no chancre. Vision has been gradually failing during the past year. There are no other symptoms. General health is good.

Ocular examination, Jan. 13, 1914, revealed right vision 20/70, left vision 20/200. Tension is normal. Pupils show marked myosis, and react to light but very slightly. Visual field: Right shows slight concentric contraction. Left also shows defect involving upper nasal quadrant. Color sense has depreciated to such an extent that the patient does not distinguish colors in any portion of field. Fundus shows nerve heads grayish-white with sharp-cut margins. Fundus otherwise normal in appearance.

APPENDICEAL INFLATION

C. C. WALLER, M.D.

LYNDONVILLE, VT.

General examination, Jan. 14, 1914, is negative except for absence of left knee-jerk. There is no anesthesia or incoordination. Wassermann reaction is positive. During the period in which patient was under treatment he was seen frequently and the visual fields were charted many times.

Jan. 23, 1914, 0.9 gm. neosalvarsan intravenously. No reaction. January 24, 30 c.c. 40 per cent. serum in normal salt solution intraspinally. Very little reaction. February 10, 0.9 gm. neosalvarsan intravenously. No reaction. Serum unsatisfactory. February 17, 0.9 gm. neosalvarsan intravenously. No reaction. February 18, spinal injection of 30 c.c. 40 per cent. serum. Little reaction. Subjective improvement in vision. March 14, 0.9 gm. neosalvarsan intravenously. March 15, 30 c.c. 40 per cent. serum intraspinally. March 27, intravenous injection of 0.9 gm. neosalvarsan. March 28, spinal injection of 30 c.c. 40 per cent. serum. April 4, 0.9 gm. neosalvarsan and 30 c.c. 40 per cent. serum. In this case no reactions of any kind followed the intravenous injections of neosalvarsan, and very slight reactions followed the intraspinal injections of serum. These consisted of some pain in head and back of neck. Examination following last treatment showed a slight left knee-jerk. April 24, it was found that while visual acuity, as shown by ability to read test letters, had improved but little, the sector defect in left field had disappeared and patient was beginning to distinguish colors. May 24, vision is: right $\frac{20}{50}$; left $\frac{20}{100}$. Color fields were mapped with 1.5 cm. test object.

CASE 2.—R. W. L., man, aged 37, single, machinist, with negative family history, thirteen years ago had some skin trouble with possible chancre. Patient does not know what diagnosis was made. History otherwise was negative up to two years ago, when vision of right eye began to fail. Vision of left eye began to fail a few months later. For several months right eye has been totally blind. Sight of left has constantly grown worse. Patient had lancinating pains about six months ago.

Ocular examination, February, 1914, revealed right amaurosis. No light perception present. Left vision $\frac{20}{100}$. Entire upper half of visual field wanting. Pupils slightly dilated, right does not react to light directly but consensual reaction is present; left reacts to light very slightly. Patient cannot distinguish colors.

General examination, March 2, 1914, revealed absence of knee-jerks, presence of Romberg sign and marked incoordination of both upper and lower extremities.

March 3, 1914, 0.9 gm. neosalvarsan intravenously. Serum obtained was unsatisfactory. March 10, neosalvarsan 0.9 gm. intravenously. March 11, 30 c.c. of 40 per cent. serum in normal salt solution intraspinally. Quite severe pain in head and back lasting several days. Subjective improvement in vision followed subsidence of reaction. March 24, neosalvarsan, 0.9 gm. intravenously, some leakage occurring outside of vein. March 25, 30 c.c. of 40 per cent. serum intraspinally. Infiltration of right arm at site of injection. April 7, neosalvarsan, 0.9 gm. Ulceration present at site of previous injection on right arm. April 8, 20 c.c. of 40 per cent. serum intraspinally. April 21, patient's visual field was practically the same as when first examined but vision had improved markedly. He read $\frac{20}{40}$; 0.9 gm. neosalvarsan intravenously and 30 c.c. of 40 per cent. serum intraspinally. Quite a severe reaction followed with pain in back, legs and chest. Right arm improved. April 25, subjective vision worse. May 4, subjective vision improved again. Neosalvarsan, 0.9 gm., intravenously and 30 c.c. of 40 per cent. serum intraspinally. Severe reaction followed in a few days. May 18, arm healed. Examination showed that coordination was noticeably improved. Knee-jerks absent. Practically no reactions followed the intravenous injections in this case. May 20, 1914, patient read $\frac{20}{30}$ easily and guessed several letters at $\frac{20}{20}$. Patient now distinguished color, and color fields were mapped with 1.5 cm. test object.

This case is especially interesting because of the rapidity with which sight was being lost and the marked improvement which took place following the intraspinal injections.

This title is open to criticism, but it serves the purpose of introduction to an interesting observation made by myself and assistants at the Brightlook Hospital, St. Johnsbury, Vt.

Nov. 17, 1913, a girl, aged 8, while at stool was suddenly seized with violent cramps in the abdomen, and in a few moments became unconscious, but rallied soon after; nausea and vomiting followed, relieving her distress. Twenty minutes after this attack, I found her exhibiting exhaustion and pallor. The temperature, 98, was subnormal; the pulse was 100; there was slight tenderness in the right quadrant; the bowels were constipated. Her parents informed me that during the past two years attacks similar to this, though not so severe, had occasioned no anxiety, and that the patient had maintained her usual health though she had complained of slight stomach disturbances more or less during this time. I suspected chronic appendicitis with adhesions, perhaps, involving the ileum to a point of partial obstruction.

Acting on my advice the parents consented to an operation, November 20. At the operation I proceeded in the usual manner, and on delivery of the appendix the patient, not being fully anesthetized, began straining with considerable energy, and to my surprise the apparently inoffensive and normal appendix began to inflate to a degree near bursting. With a gauze pad near-by I grasped with both hands the ballooning member to prevent what I felt surely to be impending disaster, and held it until the patient became relaxed, when to my further surprise, I found it necessary to exert gentle pressure to deflate the 2-inch inflation. After removal, I found within the appendix a No. 6 bird shot. No inflammatory changes were observed adjacent to or within the appendix.

This, to my mind, in an emphatic way accounts for many heretofore puzzling phenomena as observed when on operating we have found so little to account for the intense suffering and apparent seriousness of acute cases of ileocecal colic, the appendix usually containing small concretions or foreign bodies.

That the appendix, under favorable conditions, may become enormously inflated is a fact, as in the case noted above. The shot (a fecal concretion may serve in a like manner) occluded the appendix lumen as a ball-valve, preventing ready deflation and thereby causing intense pain and attending phenomena, all of which were, in this case, under authentic observation.

Enforcing Sanitary Laws.—What is true of laws in general is equally true of sanitary laws. Many so-called sanitary and public health laws now on our statutes are an obstacle to progress in preventive medicine. Many good sanitary laws are not enforced and cannot be enforced because public sentiment is not fully alive to the importance of preventive medicine. The natural result of this apathy is a withholding of proper authority and proper appropriations by means of which laws can be enforced. Hence, laws fail in their purpose. One of the greatest needs in efficient public health work in the United States is a national Department of Health, a great central educational institution for research, for information, for cooperation. There must be a well-organized national health department in which must center every function of the government in any way touching public health. The aid and cooperation of this department must be available to every citizen, every community and every city and state board of health in all public health problems, even as the aid of a national Department of Agriculture is now available to every farmer and every farming community. —W. THE NORMAL AND PATHOLOGIC OCCUR- RENCE OF CHOLESTEROL

Any one who reads the literature of modern medicine must be impressed with the growing importance of cholesterol and its derivatives. In connection with the problems of hemolysis and other features of immunochemistry and in relation to various aspects of pathology, this lipid substance has received detailed consideration. Some of the views developed in this connection have found expression in *THE JOURNAL*.¹ In dealing with any component of the organism which is supposed to have importance either in health or disease, it sooner or later becomes desirable to gather statistics concerning the occurrence and distribution of the substance. In the case of cholesterol, few data have been collected as yet by the more recent reliable methods of analysis. From such facts as have been gathered the impression has been gained that the cholesterol content of the individual organs is fairly constant. The newest researches of Thaysen² conducted in the Universities at Lund in Sweden and Copenhagen in Denmark, cast doubt on the current belief. The examination of a considerable number of organs and tissues of healthy animals indicates an unexpectedly wide variation in the content of cholesterol and its esters, respectively. The red blood-corpuses alone furnish an exception with respect to this variability.

It is too early to predict the significance of these unexpected facts. Wide differences in the content of any tissue constituent in conditions of health are sometimes taken as a suggestion that the substance under consideration is an incidental rather than an essential component; otherwise a greater uniformity in the amount present might be expected. The quantity of fat, for example, in the tissues varies widely; whereas the sugar in the blood, the water in the glands, the acid in the gastric juice are instances of the fairly

unchanging presence of indispensable physiologic compounds. This mode of reasoning is, however, far from convincing in any attempt to ascertain the significance of a tissue substance. Further data must be awaited.

In another respect, likewise, the cholesterol situation has experienced a change through recent investigations. Certain pathologists, notably Aschoff of Freiburg and his pupils, have classified a group of pathologic fat accumulations under two types: one the glycerol-ester or true-fat type, the other, the cholesterol-ester variety.³ The conclusions appear to be based largely on the results of purely histologic examinations of tissues. By chemical analyses of a large number of normal and "fatty" organs, however, von Czyhlarz and Fuchs⁴ have failed to discover any unique or undue occurrence of cholesterol esters in comparison with the usual fatty substances in cases in which they might be expected to occur on the basis of the reputed morphologic evidence. Until the chemist and morphologist, each using his own suitable procedure of examination, can agree with respect to the alleged existence of the cholesterol types of fatty degeneration or infiltrations we prefer to adhere to the older views regarding the fatty accumulations.

PELLAGRA AND POTABLE WATERS

The belief that there is an etiologic relationship between water and pellagra is not new. Numerous and varied theories have been offered as to the nature of such a possible relation. Quite unique among these hypotheses, however, is the belief that drinking-water, because of the presence of certain chemical constituents, may be of consequence in the causation of pellagra.

A preliminary note on the relation to pellagra of potable waters containing silica in colloidal solution was first presented by Alessandrini and Scala¹ about a year ago. In a recent monograph of nearly two hundred pages² their views and work are presented at length. In 1909 Alessandrini³ began, in Italy, a series of epidemiologic studies on pellagra which led him to regard the disease as etiologically related to potable waters used in pellagrous sections. He first advanced the idea that pellagra was a filarial infection derived from such waters. Subsequent fuller investigation forced him to abandon this supposition, but left him still convinced of the etiologic connection. He associated with himself a chemist (Scala) who, after

much investigation, "formulated the suspicion that silicic acid, dissolved in a colloidal state, could produce a chronic intoxication such as is observed in pellagra." The present monograph is an attempt by these two authors to establish the truth of this suspicion or hypothesis.

Since silicon of whatever form in water must be derived from the soil, the writers discuss the relation of soils to waters and give in detail their method of preparing the colloidal solutions and the gelatinous suspensions of silica used in the experiments. In this study they made use also of potable waters obtained from certain pellagrous sections.

Their experimental work was conducted on guinea-pigs, rabbits, dogs and monkeys. It consisted in the injection and ingestion of the above-mentioned solutions and waters along with numerous variations in the diet of the animals, especially with reference to a diet of maize. In some experiments they made additions to their solutions of certain salts, notably of calcium, sodium and aluminum, for the purpose of testing the action of certain electrolytes on the colloidal silica or of the contemporaneous action of the two (that is, colloidal silica and electrolytes) on the organism. Full protocols with histopathologic findings as well as photographs and charts make the report of their experimental work very complete.

In an analysis and discussion of the results, the authors express the conviction that they have produced in their animals a chronic intoxication which not alone in essential features but even in details closely approximates pellagra as seen in man. This they assert is true not only of clinical phenomena but also of morbid pathologic changes.

Their analysis of the pathogenesis of the condition produced in their experimental animals (and of pellagra as well, of course) consists of an elaborate chemical discussion to which scant justice can be done in limited space. A mere outline must serve to show the basis of their argument. Colloidal silica displays more or less affinity for mineral salts and, from metabolic studies on dogs under experiment, Alessandrini and Scala concluded that "without doubt silica in the animal organism acts by accumulating mineral substances and produces in consequence a destruction of tissues." Tracing farther the various chemical changes and relations which, according to them, the silica undergoes, their next conclusion is, "Therefore it seems to us without doubt that the silica fixes the mineral salts on the proteins of the tissues with a continuous, incessant action quite similar to the action of an enzyme or diastase." Carrying the subject a step farther, they think that "conditions exist in the formation of these compounds of protein substances with mineral salts by which the acids of such salts are liberated, because there is a tendency in said compounds to pass from the state of metallo-acido-protein to that of metallo-protein." By further

analysis, argument and experimentation they arrive at their final conclusion, that "pellagra is a malady caused by the forced retention of mineral salts which in turn produces a liberation of acids in excess of the needs of the particular organism; or, in other words, pellagra is nothing more than a mineral acidosis with all of its consequences."

These conclusions, the writers point out, are supported by the metabolic studies made on pellagra by various Italian students, such as Camurri,⁴ Nicolaidi and Grillo,⁵ Moreschi⁶ and others.

Having established to their own satisfaction that "pellagra is a mineral acidosis," the natural treatment would of course be some alkali. For therapeutic use sodium citrate was "selected because it could be used by intramuscular injection without injury, is not caustic, and circulates freely in the tissues, forming by oxidation sodium carbonate, which serves to neutralize the acids present." After preliminary experiments on dogs, several pellagra patients were treated with this substance. Daily injections were given in the gluteal muscles, of 1 c.c. of a 10 per cent. solution. The results were distinctly encouraging in selected cases (that is, comparatively recent cases before permanent damage is done to the tissues).

The prophylaxis of pellagra, if this view is confirmed, resolves itself into the question of supplying communities with suitable potable waters. Some practical suggestions are offered by Alessandrini and Scala for this purpose, the chief of which is that calcium carbonate dissolved in water precipitates the silica which may be present.

Among their general conclusions it may be stated that they lay some stress on the influence of certain electrolytes with which the colloidal silica comes in contact; and they think that alumina, whether in colloidal combination or in a state of simple suspension in water, probably has an action similar to the silica, or at least may aggravate the condition caused by, or reinforce the effects of, the latter. This is of some interest in view of the recent note of Myers and Voegtlin⁷ as to the presence of aluminum salts in certain foodstuffs.

Whatever opinion may be entertained concerning this theory, Alessandrini and Scala have certainly brought to its support an apparently arduous and consistent piece of work. This is far more than can be said of many another idea put forward to account for this disease. Moreover, it would seem comparatively easy in this country to gather at least strong presumptive evidence for or against their view by chemical analyses of the potable waters found in sections in which pellagra is prevalent.

THE MARINE BIOLOGICAL LABORATORY AND
MEDICINE

The dedication of the new buildings of the Marine Biological Laboratory—the gift of the President of its Board of Trustees, Mr. C. R. Crane—at Woods Hole, Massachusetts, July 10, deserves more than incidental notice in medical circles. Louis Agassiz, in America, and Anton Dohrn, in Europe, were among the first to organize seaside laboratories offering opportunities for biologic investigations that are unique. Dohrn's station at Naples has become a Mecca for students from all parts of the world; and the institution at Woods Hole, which is, in a sense, a lineal descendant of Agassiz's original plant at the island of Penikese, founded in 1872, promises to have a usefulness scarcely inferior to that of the European seaside laboratory.

The interrelations of biology and medicine have become so clearly established in recent years that they no longer demand emphasis even before an audience of practitioners. A biologic training has become recognized as one of the indispensable fundamentals on which the study of medicine is properly reared. Biology is related not only to the affairs of every-day life, but also to the routine of medicine, in which it furnishes the indispensable foundation. Hygiene and the disciplines of public health rest on biologic factors. One aspect of modern biology—the cell theory—is an adequate illustration of how a single great generalization in this comprehensive science has revolutionized the study of pathology and physiology, the very basis of medicine. For this reason medicine can only look with pride and interest at the development of new places and instruments for biologic research and at the promise of increased benefits and new discoveries which shall contribute to the advancement of our profession. The Marine Biological Laboratory deserves especial mention, furthermore, for the splendid example which it has furnished of opportunities for investigation that shall be unrestricted by the dictates of custom, inherited prejudices, or the unconcealed demands of local interest and sectional factions. Its progress has been an indication of the stability and permanence of a democratic organization in which freedom has been the dominant character—the freedom of a democracy of learning, as it was termed by one of the speakers at the dedicatory exercises. Freedom of organization, he added, is our one watchword. Cooperation is another. Both are vital and they are interdependent. And so we have, at Woods Hole, a union of forces of scientific men, and through them of institutions that they represent, in order to create conditions as ideal as possible for the progress of science.

In the dedicatory address, on "The Needs of Research," Dr. R. S. Woodward,¹ the president of the Carnegie Institution of Washington, called attention

to how far the popular mind, and how far many disciplined minds, may depart from the meaning we attach to the term research. Even in medical circles one may find indications of false ideas of what the term comprehends. Although an appreciation of the advantages of the spirit of patient investigation over that of stolid conservatism, on the one hand, or reckless inquiry on the other, is making itself manifest widely, there are still many who look on research as a sort of irrational achievement. We should never forget, says Dr. Woodward, that the investigator lives usually in the presence of majorities which do not understand him and that progress is largely conditioned by these majorities. Thus, to journalists and to their readers it would seem that research is akin to necromancy and that its results are produced chiefly by witches of the male sex, otherwise designated in the polite literature of our day as wizards. Closely akin to this infantile fallacy, Dr. Woodward adds, is the more subtle error entertained by a majority, perhaps, of our highly educated contemporaries, that the more remarkable results of research are produced not by the better balanced minds, but by aberrant types of mind popularly designated by that word of ghostly, if not ghastly, implications, namely, "genius."

Men of science are on trial in these days. Money is being furnished lavishly for the endowment of research institutions and the promotion of investigation. It is important to take advantage of the current favorable attitude on the part of a helpful portion of the public and encourage its enthusiasm for the modern research enterprises. The Woods Hole Laboratory certainly represents the latter worthily.

A NEW SERUM REACTION FOR THE DIAG-
NOSIS OF GASTRIC CARCINOMA

Recently several serum tests for the diagnosis of carcinoma have been proposed. Among these may be mentioned Abderhalden's test for specific ferments for cancer-cells, Brieger and Trebing's antitrypsin reaction, the miostagmin reaction of Ascoli, Crile's isolysin reaction and von Dungern's complement-binding reaction. In the hands of careful workers experienced in the special technic, each of these methods seems to demonstrate a substance in the serum of cancer patients which reacts more or less specifically on a substance contained in cancer tissue; but none of the methods hitherto proposed has seemed by virtue of its reliability of result and simplicity of technic to merit general adoption as a diagnostic measure. This does not mean that such a method may not be found, or that further improvement in some of these methods may not make them suitable for general use.

Recently Kelling¹ described a test which in the matter of simplicity answers all practical requirements,

1. Woodward, R. S.: The Needs of Research, Science, Aug. 14, 1914, p. 217.

1. Kelling: Wien. klin. Wchnschr., 1914, xxvii, 927.

being essentially much simpler than the simplest modification of the Wassermann reaction. Whether or not it will meet the requirement of accuracy of result must be determined by further tests. While experimenting on heterolytic serums, Kelling observed that the serum of cancer patients possessed the property of dissolving the red corpuscles of certain other species, notably the hen. The presence of an inhibiting substance in some serums and of lysins in some normal serums prevented the use of the test in this form for diagnostic purposes. These sources of error were obviated by diluting the patient's serum 1:10 with physiologic salt solution and incubating for twenty-four hours at 37 C. (98.6 F.). Equal parts of this diluted serum and a 5 per cent. suspension of hen corpuscles were then incubated for from twenty-four to forty-eight hours and the hemolysis noted. In what way the incubation of diluted serum eliminates the inhibiting substance, which seems to be the case, the author does not explain. It was found that this modification gave positive reaction in about 90 per cent. of cases of gastric carcinoma. As controls, serum from patients in all conditions which require differential diagnosis from carcinoma were used, and also normal serum. Kelling reports a consecutive series of 250 cases of common diseases of the gastro-intestinal tract tested by this method. Among these are sixty-five cases of carcinoma, of which fifty-eight, or about 90 per cent., are positive. Of the 185 other conditions, six cases, or less than 3 per cent., give positive reactions. These six include suppurating cholecystitis, tuberculosis of the peritoneum, appendiceal abscess, tuberculosis of the intestines, "influenza gastrica" and an anemia in which the patient had repeatedly received normal human blood by transfusion.

Kelling finds that a combination of the serum reaction and the miostagmin reaction of Ascoli is of advantage, as the two do not give errors in the same types of conditions.

Another combination which he recommends and which in his series of cases gives 100 per cent. positive in gastric carcinoma with 0 per cent. positive in controls, is with the test for occult blood in the feces. The test for small quantities of blood in the stools evidently is not specific for carcinoma, but the combination of this with the serum test seems to reduce the percentage of error.

Evidently this test is not etiologically specific; but neither is the Wassermann test, which uses as antigen an extract of non-syphilitic tissue. We are unable to explain the biochemical principles which underlie many clinical tests, but this is not sufficient reason for rejecting them if trial proves their merits. Kelling rightly maintains that, in general, no diagnostic test is expected to give accurate results in 100 per cent. of the cases, and that no single test is sufficient basis for a diagnosis; that any test should be regarded as additional evidence, while the diagnosis rests on the sum of

all the evidence. Obviously the lower the percentage of error in a given test the greater is its weight in the sum of the evidence.

A simple laboratory procedure which will be of service in detecting early carcinoma of the stomach will receive a hearty welcome by the medical profession. Further reports on the use of the serum test described by Kelling will be awaited with much interest.

THE PURINS AND ALIMENTARY BACTERIA

One of the experimental difficulties that have been encountered in attempting to explain the transformations of the nucleoproteins and their derivatives, the purin substances, in the organism has consisted in the fact that the total intake of these compounds could rarely be accounted for in the outgo. If, for example, a known quantity of some purin such as hypoxanthin, xanthin, guanin, or even uric acid be ingested, the increased excretion of the supposed end-product of this series ordinarily falls short of what would be expected if the oxidative conversion had been complete up to the uric acid stage in the body. This fact has repeatedly been demonstrated in man. When extract of meat, a product comparatively rich in hypoxanthin derived from muscle tissue, is consumed, the increase in uric acid or other purins in the urine will rarely account for more than about one-half of the purin of the food intake. For this reason it was assumed and taught for a long time that the production and destruction of uric acid proceed simultaneously in the organism. Accordingly the amount found in the urine at any period was believed to represent the balance between these two antagonistic processes.

When, however, it was observed that the introduction of either purins or uric acid into the body parenterally, instead of orally, resulted in a much larger consequent output of uric acid, another explanation suggested itself. Siven¹ argued that perhaps ingested purins are destroyed in considerable part within the alimentary tract through the agency of bacteria. When taken into the body by way of the mouth, therefore, the quantities that would actually be absorbed after escaping the possibility of loss through microbial degradation might be decidedly smaller than the original intake; hence the output would be correspondingly diminished. Injected purins, on the other hand, would be protected from such destruction and consequently reappear quantitatively as uric acid, their end-product.

Although no serious obstacle has stood in the way of explaining the disappearance of purins taken by mouth in the way just outlined, certain observations have not spoken in its favor, to say the least. It has been known that bacteria can decompose purin compounds, but the evidence has given the impression that

1. Siven, V. O.: Ueber den Purinstoffwechsel des Menschen, Arch. f. d. ges. Physiol., 1912, xciv, 283.

this change is not easily accomplished². A renewed investigation of the subject by Siven³ leaves no doubt that a very considerable amount of purins can undergo prompt destruction through the action of such organisms as *Bacterium coli*, and under conditions such as are believed to exist in the digestive tube. We may safely conclude, therefore, that a liberal proportion—as much as 50 per cent. in some cases—of the purin intake can lose its identity before it has had a chance to be absorbed from the gastro-intestinal tract. Whatever enters the blood-stream, however, doubtless escapes destruction and thus forms the precursor of the exogenous uric acid of the urine.

THE PRICE OF CARELESSNESS

The commonplace gains enormously in impressiveness when familiar and long-recognized facts are collected and tabulated. Fourth of July accidents were regarded as inevitable and of comparatively small importance until THE JOURNAL undertook the systematic collection and compilation of the statistics. Presented in the aggregate, they shocked the nation. The American people have long been accustomed to accounts of railroad accidents in the public press. It is only the occasional accident of startling character or unusual magnitude which arouses comment. The public does not appreciate the enormous toll which is paid every year in loss of life and limb because of avoidable accidents on our railroads.

Accident Bulletin 50, just issued by the Interstate Commerce Commission, contains a summary of the accidents resulting in personal injuries caused in the operation of interstate railways during the months of October, November and December, 1913. The facts presented are so appalling that if they were found anywhere else than in a government publication they would be regarded as extreme exaggerations. During these three months, 2,792 persons were killed and 50,776 persons were injured in connection with railway operation. Of these, 191 were killed and 3,726 injured in train accidents; 2,675 were killed and 21,769 injured in accidents other than train accidents, such as fires, floods, landslides and explosions affecting the right of way, and accidents in connection with railroad operation other than those of trains and roadway, while 117 deaths and 29,007 injuries were industrial accidents to employees working on tracks, bridges, stations, engine-houses, shops, wharves or elsewhere. Of the 2,792 persons killed, thirty-four were passengers killed in train accidents, and 137 were employees killed in train accidents. Eighty-five passengers were killed from all causes and 730 employees from all causes, making a total of 815 passengers and employees. The 1,860

other persons killed included trespassers, non-trespassers and employees not on duty, while 117 employees in addition were killed in industrial accidents not connected with railroad operations.

Detailed tables showing the cause and character of the accidents are most interesting and illuminating. For instance, of the 21,769 persons injured through train and other accidents, five persons lost their eyesight, ninety lost arms, forty-seven persons lost their hands, 213 persons lost legs, 143 persons lost feet. Many of those crippled will be incapable of supporting themselves for the balance of their lives and will consequently become dependents. The total loss of working time due to accidents is not shown. With over fifty thousand persons injured in three months, however, the economic loss must be enormous. At this rate there are probably nearly twelve thousand persons killed and over two hundred thousand persons injured every year on our railroads. The majority of these accidents are avoidable either through proper safety devices supplied by the operating company or through care in operation on the part of employees. The price paid for carelessness as shown by the official statement of fact is too enormously heavy to be tolerated.

Current Comment

OHIO IN LINE

One of the most readable and progressive medical journals published by any state organization is the *Ohio State Medical Journal*. It is characterized not only by the scientific value of its articles, but also by the "snap" and "life" which permeate its various departments and especially by the way in which it serves up its state news and matters of interest to the local field which it covers. In fact, the only just criticism that might have been made of this journal was that concerning the standards which governed the admission of advertising matter. This criticism is now removed, for in its August issue the *Ohio State Medical Journal* says in part:

We will not, in the future, print the advertising announcement of any medicinal product that has not received the sanction of the Council on Pharmacy and Chemistry of the American Medical Association.

In other words, *The Journal* will no longer boost unethical nostrums.

Furthermore, we will not print the announcements of sanatoria that are not operated on ethical lines; or of any product, medicinal or otherwise, that does not make a true statement of its value, or does not offer the intending purchaser a "square deal."

We believe that this will make our advertising columns much more valuable to our readers.

This move speaks well for the Ohio profession. As has been said many times, the immediate result of raising the standard of admissible copy to the advertising pages of any journal is a falling off in revenue. This means that the medical profession of Ohio must give its official publication active, moral and financial support.

2. Schittenhelm, A., and Schröter, F.: Ueber die Spaltung der Hefenucleinsäure durch Bakterien, *Ztschr. f. physiol. Chem.*, 1903, xxxix, 203; 1903, xl, 62; 1903, xl, 70; 1904, xli, 284.
3. Siven, V. O.: Ueber den Purinstoffwechsel des Menschen, iii, Mitteilung, *Zur Frage der Spaltung der Purinkörper im Verdauungskanaal*, *Arch. f. d. ges. Physiol.*, 1914, xlvii, 582.

There are, to-day, twenty-three state journals and six privately owned medical journals that have adopted the standard of the Council on Pharmacy and Chemistry as regards proprietary medicine advertisements. These journals are proving that the standard of decency is not an impracticable one. May the physicians of Ohio rally to the support of their journal; they can render no more effective service in the fight against medical fraud and in behalf of scientific medicine.

DIPHTHERIA ANTITOXIN

It may be thought by some that the whole question of the use of antitoxin in diphtheria is settled. Nevertheless, it may be worth while to emphasize certain factors that are not always borne in mind in using it. The chief ones are the quantity to be given and the time and method of administration. The average dose is given in the Pharmacopeia as 3,000 units. While probably a sufficient initial dose in many cases, this quantity is not enough to satisfy the factor of safety. Although 3,000 units will neutralize the toxins formed in the human organism in an average case, it must be remembered that some time elapses before complete absorption takes place and hence before all the antitoxin becomes effective. Meanwhile the average case at the time of injection has become a severe if not a fatal one. A severe case terminating fatally might have remained a mild, average case had a larger initial dose been given. There is a daily growing sentiment that the amount necessary to effect a cure should be given in one dose at the earliest possible hour. Woody¹ states that "no case of diphtheria, however mild, should receive less than 10,000 units." His experience covers almost ten thousand cases and shows a reduction in mortality of 3 per cent. when large doses are used as compared with smaller ones. The point is emphasized by Anderson² that 10,000 units are of more value when given early than 100,000 or 200,000 when given later. It is safe to say that 10,000 units would be much nearer the average dose used in the large metropolitan hospitals than the 3,000 units stipulated in the Pharmacopeia. Although promptness of administration after the onset of the first signs and symptoms has been proved to be the most important element in the successful use of antitoxin treatment, there must be considered as well the method of injection. Smith³ and Park⁴ have shown that when the subcutaneous route is used, the maximum amount of antitoxin is found in the circulating blood only after three or four days. If antitoxin is given intramuscularly this period is of course shortened. It is still further shortened by intravenous injection, which method has been advised for extremely severe cases. When this extreme method is adopted a much smaller amount of antitoxin is required, as action is immediate. It cannot be too often emphasized that antitoxin must be given early; that with a small patch of membrane a smaller dosage may be required than when a complete laryngeal, pharyn-

geal and nasal involvement exists, and that the subcutaneous injections are more slowly absorbed than deep intramuscular ones. The authority of the Pharmacopeia, in its forthcoming revision, should be lent to the aid of experience by stipulation of a larger average dose—for example, 10,000 units—and a sliding scale to inform the physician that the great quantities are sometimes essential.

WAR AND PREVENTIVE MEDICINE

Our Paris correspondent has not written since the declaration of war—August 1. The London *Lancet* of August 22 contains a last word from its Paris correspondent, concerning the beginnings of the war as they affected Paris. He writes: "The greater number of medical men, even those of mature age, in Paris have already gone to take their posts in the Army Medical Service, and your own correspondent is writing you this, his last letter for some time to come, only a few hours previously to his departure to take charge of an ambulance corps, as *médecin chef* in the Army of the East." Lists of medical men remaining in Paris, with their addresses, have been posted in each quarter of the city. Many hospitals have been evacuated and their patients assigned to others. The remaining hospitals care for the wounded, who are already beginning to arrive. Most of the wounded will not be taken to Paris, as this city may perhaps be placed in a state of siege, but are being carried to more distant points. The Faculté de médecine has also been converted into an ambulance station, as well as all the lycées and the public and private schools. Great fear has been expressed by Professor Chantemesse lest infectious diseases should break out in epidemic form. A general revaccination of the population of Paris has been ordered, and huge quantities of antityphoid serum have been prepared.

SOME FACTORS AFFECTING FETAL DEVELOPMENT

Some weeks ago we commented¹ on recent experiments of Bailey and Murlin² who have shown that the initial loss of weight in the first few days following birth may be prevented by extra feedings of a formula of the same composition as the colostrum. In view of the fact that the infant, during gestation, must be affected by the nourishment of the mother with whose metabolism its own is so closely bound, Evvard³ has undertaken experiments to show to what extent this influence may operate. A number of gilts (young sows, prospective swine mothers) were fed on different foodstuffs. The basal ration was corn alone, which is quite deficient in protein and calcium. As supplements were used meat-meal, containing about 60 per cent. protein, 15 per cent. ash and 10 per cent. fat, also clover and alfalfa. The latter substances also contain large quantities of protein and calcium. It was found that in every case the supple-

mented rations resulted in pigs which were larger and stronger at birth than when an equal weight of corn alone was fed. The character of the coat also was better when oil-meal was used than when meat-meal was given. Thus Evvard states that oil-meal has been noted from time immemorial as a coat producer. On the other hand, meat-meal invariably produced larger-boned offspring than did other types of food. The same experiments were carried out with sheep, and it was again shown that the ration tends to affect in some manner the size and vigor of the offspring although the differences are not so marked as when swine are fed entirely on grain. An outlook for further important conclusions is opened up by these experiments. The possibilities are numerous. The production of a quickly-growing, vigorous offspring will offset to a great extent the numerous attacks made on the struggling infant by the diseases of infancy. The human infant is helpless for a period relatively far longer than that of other mammalia. Any knowledge which will aid to give it a more advantageous start on the difficult road it must travel represents progress in infant welfare.

Medical News

CALIFORNIA

Sanatorium Burned.—Fire starting in a defective flue destroyed the main building of the Pasadena Sanitarium, South Pasadena, with a loss of \$30,000.

European Travelers.—Drs. Charles H. Whitman and Orville O. Witherbee, Los Angeles, and Drs. Andrew W. and Ada S. C. Morton, San Francisco, have returned from abroad.—Dr. Aaron S. Green, San Francisco, is believed to be detained in Berlin.

Psychopathic Ward Opened.—The psychopathic building, recently erected at the Los Angeles County Hospital at an expense of \$175,000, has been completed and was formally opened August 3. The ward can accommodate one hundred patients, but only thirty have thus far been transferred.

Personal.—Dr. Raymond B. Mixsell, Pasadena, has sailed for Japan.—County Health Officer Edmund C. Sawyer, Los Angeles, was presented with a gold deputy sheriff's badge by the janitors of the county building, recently.—Dr. Alexander S. Kelly has been reelected president of the Oakland Board of Education.

COLORADO

Home from Abroad.—Drs. Frank N. Cochems, Salida; Dr. and Mrs. Leonard Freeman, Denver; Dr. Caleb W. Presnall, Trinidad, and Dr. and Mrs. Daniel G. Monaghan, Denver, have returned from abroad.

Colorado Physicians Abroad.—Dr. and Mrs. Edgemont D. Welsh, Colorado Springs, sailed for Glasgow, August 25.—Dr. and Mrs. Samuel Caldwell, Colorado Springs, are believed to be in Vienna.—Dr. William A. Kickland and family, who have been in Germany, have reached England.

Personal.—Dr. William B. Davis has returned from his post of duty as vice-consul of the United States at Guadalajara, Mexico.—Dr. James A. Rutledge, Woodmen, has been elected medical director and superintendent of the Colorado Sanatorium, Woodmen.

State Association Meeting.—The annual meeting of the Colorado State Medical Association will be held in Boulder September 9 to 11 under the presidency of Dr. Oscar M. Gilbert, Boulder. The sessions of the organization will be held in the Physicians' Building and in the University of Colorado.

FLORIDA

New Officers.—Manatee County Medical Association at Tampa, August 8: president, Dr. John B. Leffingwell, Bradenton; secretary, Dr. Hol-

Bids for Laboratory Building.—Advertisements have been made by the State Board of Health for bids on the public health laboratory building for the board to be erected at Pensacola at a cost of \$20,000.

Open Air School.—The Florida Open Air School of which Dr. William M. Stinson, Jacksonville, is vice-president, an institution devoted largely to outdoor sports and exercises, will open in Jacksonville October 1.

Personal.—Dr. Hiram Byrd, Port Orange, formerly assistant state health officer, has been appointed president of the Florida Tuberculosis Sanatorium, Trilby.—Drs. William P. Adamson, John S. Helms and Louis A. Bize, Tampa, have returned from abroad.—Dr. James M. Jackson, Jr., Miami, has been appointed a member of the Malaria Committee of the National Drainage Congress.

GEORGIA

New Officers.—First District Medical Society at Savannah: president, Dr. Herman W. Hesse; secretary-treasurer, Dr. Charles Usher, both of Savannah.

Home from Abroad.—Dr. William L. Davis, Albany; Dr. Marion C. Pruitt, Atlanta, and Dr. George R. White, Savannah, have returned from Europe.

Personal.—Dr. DeWitt C. Gilles of the staff of the Bureau of Animal Industry to the United States Department of Agriculture, as the result of a tentative examination, has been appointed chief food inspector to the Board of Central Commissioners of Savannah.—Dr. Carl C. Aven has been appointed chief of clinics at the Atlanta Medical College.—Dr. Clifford A. Peacock has been appointed medical inspector of the schools of Columbus.—Dr. Sidney Walker has been appointed local surgeon at Dublin for the Wrightsville and Tennville Railroad, succeeding the late Dr. Ezra New.

IDAHO

Personal.—Drs. Clifford M. Cline, Idaho Falls, and Franz H. Brandt, Boise, have returned from abroad.—Dr. Charles L. Gritman, Moscow, and Dr. and Mrs. William F. Howard, Pocatello, have sailed for Europe.

County Society Organized.—The president and secretary of the Idaho State Medical Association met with the physicians of Bonner County at Sand Point, July 6, and organized the Bonner County Medical Association, electing the following officers: president, Dr. Ones F. Page, Sand Point; vice-president, Dr. Leseir J. Stauffer, Bonner's Ferry, and secretary-treasurer, Dr. Charles P. Stackhouse, Sand Point.

ILLINOIS

New Hospital.—A new hospital has been opened by A. W. Chandler in Rochelle as a public institution. It is open to all regular practitioners.

Home from Europe.—Dr. Charles B. Horrell, Galesburg, has returned from Europe.—Dr. George N. Kreider, Springfield, sailed from London on his return, August 22.

Werner Improving.—Dr. Frederick W. Werner, Joliet, who has been critically ill with septicemia at the Silver Cross Hospital, Joliet, is slowly improving although not yet out of danger.

Higher Requirements.—In the schedule of minimum requirements issued by the State Board of Health, August 4, this clause is included, "No medical college shall be considered in good standing for the purpose of the Illinois Medical Practice Act, that does not require after July 1, 1918, of all students, excepting graduates of colleges of arts or science to whom advanced standing is given, in accordance with the requirements of this board as a condition of graduation, an attendance on five full courses of lectures in five separate years."

Chicago

Resigns Professorship.—Dr. W. A. Newman Dorland has resigned as professor of obstetrics in the Bennett Medical College.

Home from Europe.—Dr. Truman W. Brophy and daughter; Dr. Franklin H. Martin and niece; Dr. Samuel Salinger and Dr. James P. Way have returned from abroad.

Chicago Physicians Abroad.—Dr. Oscar T. Roberg, who has been in Berlin, has reached Sweden on his way home.—Dr. and Mrs. Peter C. Schenkelberger are detained in France, and Dr. and Mrs. Frederick Owsley have reached London from Berlin.

IOWA

Personal.—Dr. Percy B. Battey, Farragut, has been appointed a member of the medical staff of the Iowa State Hospital, Independence.—Dr. William H. McClain, has been appointed postmaster of Conrad.

More Land for Epileptic Colony.—It is announced that the State Board of Control intends to dispose of sixty acres of land at the site of the State Epileptic Colony, Woodward, and will purchase 160 acres additional more suitable to the purposes of the colony.

In and From Europe.—Dr. Daniel L. Cole and family, Oskaloosa, are believed to be marooned in Germany.—Dr. Elmer P. Weih, West Liberty; Dr. John E. Brinkman, Waterloo, and Dr. and Mrs. Herman A. White, Clinton, have returned from abroad.

Child Welfare Bureau Established.—A permanent Child Welfare Bureau has been established in Iowa City by the Commercial Club and several local organizations of women. At this bureau, parents may obtain information as to the proper care of children, and any child in ill health, whose parents are indigent, will be examined and treated free of charge.

MARYLAND

Farm Donated for Hospital.—The heirs of T. Harrison Garrett have presented the Maryland Hospital for Consumptives, Eudowood, the Pleasant Plains Farm, consisting of 188 acres of fertile land adjoining the hospital property, which has been leased by the hospital for several years.

European Travelers.—Drs. William H. Welch, Baltimore, is in Bern, Switzerland.—Dr. William S. Halsted, Baltimore, returned from Europe, August 11.—Dr. Grant Ferguson of Johns Hopkins Hospital, Baltimore, sailed for Europe, August 6.—Dr. Frank Martin, Baltimore, is reported to be on the continent.

Graduates of Liberal Art Colleges.—Information from the University of Maryland School of Medicine not received in time for the Educational Number shows that ten of the 1914 graduates of that college also possessed degrees in liberal arts. Of the 3,594 graduates of medical colleges this year, therefore, there were 817, or 22.7 per cent., who also held degrees from standard colleges of liberal arts.

Suit Settled Out of Court.—The case of Mrs. Sallie Sterling Sadler, Baltimore, against Dr. George H. Riggs, Ijamsville, in which she obtained a verdict of \$6,000 on March 20, for alleged unlawful confinement in the sanatorium of Dr. Riggs, in which Judge Bond of the superior court of Baltimore granted a motion of Dr. Riggs for a new trial on the ground of excessive damages, has been agreed and settled out of court.

Society to Honor Dr. Beanes.—The Star Spangled Banner Society of Prince George County on September 3 restored, with appropriate ceremonies, the tomb of Dr. William Beanes, located at Marlboro. Dr. Beanes served as surgeon in the General Hospital, Philadelphia, during the Revolution and it was his imprisonment on a British man-of-war which prompted Francis Scott Key to visit him in the hope of securing his relief, and Key's detention during the bombardment of Fort McHenry inspired him to write the Star Spangled Banner.

MASSACHUSETTS

Home from Abroad.—Dr. and Mrs. William E. Chenery, Boston, and Dr. George Van B. Buehler, Cambridge, have returned from Europe.

Pasteur Treatment in Boston.—The State Board of Health announces that the Pasteur treatment for hydrophobia may now be obtained in Boston.

Resigns from Faculty.—Dr. Charles E. Buck, professor in pediatrics in the College of Physicians and Surgeons, Boston, has resigned, following the resignation of two trustees of the institution.

Improvements to Hospital.—The Ladies' Charitable Union of Lawrence has instituted many important improvements at the Lawrence Hospital. At present a children's ward and a new nurses' home are in course of construction and the power house of the institution is being enlarged.

Medical Examiners Appointed.—Dr. Daniel J. Finnegan, Gloucester, has been appointed medical examiner and Dr. Philip P. Moore, Gloucester, associate medical examiner for

Essex County.—Dr. A. Vincent Smith, Middleboro, has been appointed associate medical examiner for Plymouth County.

MICHIGAN

State Society Meeting.—The Michigan State Medical Society will hold its forty-ninth annual meeting at Lansing, September 9 to 11, under the presidency of Dr. Guy L. Kiefer, Detroit.

Interest in Health Train.—Record crowds have visited the State Health Special Train during its stay in the copper country. The train has now left for The Soo, Ishpeming, Marquette and other intermediate towns.

New Officers.—Upper Peninsula Medical Society at Houghton, August 13: president, Dr. James G. Turner, Houghton; vice-president, Dr. Richard A. Burke, Diorite. The next meeting will be held at the Soo.

Home from Europe.—Drs. Frank A. Kelly, Alexander W. Blain and Angus McLean, Detroit; Austin F. Burdick, Lansing; Dr. and Mrs. William F. Hake, Grand Rapids; Dr. and Mrs. William G. Bird and son, Flint, and Dr. Charles E. Boys, Kalamazoo, have returned from Europe.

Michigan Physicians Detained Abroad.—Among the Michigan physicians who are compelled to remain abroad on account of war conditions are, Drs. Max Ballin, Detroit; Dr. and Mrs. William G. Young, Grand Rapids; Dr. Eva Rawlings, Kalamazoo; Drs. Alva N. Collins and Samuel C. Hanna, Detroit; Dr. William T. Dodge, Big Rapids; Dr. Charles H. Baker, Bay City, and Dr. Rowland H. Harris and Elizabeth K. Harris, Battle Creek.

NEW YORK

State Hospital Transferred.—The Long Island State Hospital for the Insane, which has hitherto been leased from the city of New York to the state for the sum of one dollar per year, since the state act went into effect in 1893, was transferred by deed from the city to the state of New York, August 10.

Beef Tuberculosis Board.—In accordance with an act of the legislature authorizing the scientific study of bovine tuberculosis, its economic and health effects on the state, and a report with recommendations to the legislature, Governor Glynn has appointed a committee consisting of Drs. Theobald Smith, Hermann M. Briggs, Linsly R. Williams, Philip Van Ingen and Henry L. K. Shaw, together with a number of veterinarians, cattle breeders and other laymen. An appropriation of \$5,000 is available to pay the expenses of the commission which, at the governor's request, will meet immediately after the members receive their designations to complete the organization and to put the investigation under headway.

New York City

Must Give Full Time to Work.—The commissioner of health has issued an order prohibiting all heads of bureaus receiving a salary of \$5,000 or more, from engaging in any work not connected with the department.

Personal.—Drs. Abr. L. Wolbarst, George Bolling Lee, New York City, and Edward E. Hicks, Brooklyn, have returned from abroad.—Dr. Michael J. Thornton has been appointed chief of staff of the psychopathic ward of the Kings County Hospital, succeeding Dr. William B. Mosely, deceased.—Dr. Jacob Oshlag has been appointed a member of the board of managers of the Manhattan State Hospital.

City Farm for Drug Users.—A committee of city officials of which acting Mayor McAneny is chairman, have decided to ask the Board of Estimate and Apportionment for an appropriation which will enable the city to utilize a part of its Inebriate Farm Colony in Orange County as a sanatorium for drug victims. Practically all the space available in the city hospitals has been given over to this class of patients and it is realized that something must be done to prevent drug victims from crowding out other patients.

Advisory Council of Health Board at Work.—Shortly after taking office the commissioner of health appointed an advisory council in order to effect a closer contact with the public and to secure well informed criticism and suggestions from experts in public health matters. This advisory council consists of representative men and women prominent in various public health activities. At the first meeting of this council suggestions were offered as to new lines of work by the Department of Health. As a result of the discussion at that time seven committees were organized as follows:

Records, Laboratories, Child Hygiene, Infectious Diseases, Foods and Drugs, Sanitation and Public Health Education. All of these committees have held meetings and many valuable suggestions have been presented; these as far as is possible have been acted upon. It is believed that the work of these committees and of the advisory council as a whole will prove of invaluable assistance in the administration of the work of the Health Department.

NORTH DAKOTA

Medical Board of Appointments.—Governor Hanna has reappointed Drs. John E. Countryman, Grafton; Alexander J. McCannel, Minot, and Paul Sorkness, Fargo, members of the State Board of Medical Examiners.

Personal.—Dr. Ralph E. Weible, Fargo, has gone abroad. —Dr. Gustav F. Ruedeger, formerly director of the State Public Health Laboratory, Grand Forks, has returned from the West and has taken up his duties as director of the Health and Research Laboratory at LaSalle, Ill.

State Hospital Overcrowded.—The State Board of Control estimates that one-half million dollars is required for the construction of new ward buildings for the North Dakota State Hospital for the Insane, Jamestown. The institution at present has 316 more patients than its normal capacity.

OHIO

New Officers.—Morgan County Medical Society at McConnellsville, August 14: president, Dr. Leroy S. Holcomb, Pennsville; secretary-treasurer, Dr. Clarence E. Northrup, McConnellsville.

Swimming Pools Contaminated.—An investigation of the swimming pools of Columbus by the health department revealed contamination with colon bacilli in one case and insanitary conditions in others. Dr. Louis Kahn recommended that the pools be treated with chlorid of lime.

State Institutions Crowded.—Statistics gathered by the State Board of Administrations show that state institutions are not capable of caring for all the criminal and insane. Nearly 4,000 names are on the waiting lists in the various counties. When the legislature convenes the board will urge additional hospital facilities.

Summit County Health Protective Society.—The headquarters of this society are at Akron, and a campaign has been begun with the object of increasing the membership to 1,500. The society has resolved to better the sanitary conditions in Akron, and with this object in view will endeavor to secure the support of every citizen.

New Officers.—West Side Physicians' Club, Dayton, reorganized August 21: temporary president, Dr. Grant S. Staub; temporary secretary, Dr. Tedd L. Gregg. —Morgan County Medical Society at McConnellsville, August 14: president, Dr. Leroy S. Holcomb, Pennsville; secretary-treasurer, Dr. Clarence E. Northrup, McConnellsville.

In, and Returned from Zone of War.—Dr. James G. Grant, Akron, with his wife and four children, are reported to be in Berlin. —Dr. Max Stamm, Fremont, is reported to be in Bern, Switzerland. —Drs. Colin R. Clark and James A. Sherbondy, Youngstown; Dr. John V. Hartman, Findlay, and Dr. Henry K. Yaggi, Salem, have returned from abroad.

Anti-Tuberculosis Society Districts State.—The representatives of the Ohio Society for the Prevention of Tuberculosis and the Division of Tuberculosis of the State Board of Health, have divided the state into twelve tentative districts, each of which includes from four to six counties, wherein campaigns are to be inaugurated for the establishment of tuberculosis hospitals.

Sanitation and Disease Prevention Campaign Started.—The Canton Board of Health has started an educational campaign on sanitation and disease prevention. A topic will be chosen and discussed at each regular meeting of the board. Topics already chosen for present and future discussion are: "Rats and Their Relation to Human Plague"; "Pure Milk"; "Infant Mortality," and others allied thereto.

Personal.—The Secretary of the Treasury, on recommendation of the Surgeon-General, U. S. P. H. S., has appointed Dr. Eugene F. McCampbell, Columbus, secretary of the Ohio State Board of Health, collaborating epidemiologist, in the United States Public Health Service. —Dr. Edward K. Cook, police surgeon, of Hamilton, has resigned. —Dr. Stanton K. Crawford, Lakewood, has been appointed super-

intendent of the Five Counties (Columbiana, Mahoning, Portage, Stary and Summit) Tuberculosis Hospital, Springfield Lake, near Akron. The hospital will probably be ready to receive patients early in October. —Dr. Robert C. Paul, Shreve, announces that he will soon move to Wooster, where he will succeed Dr. Kate M. C. Johnson as superintendent of a private hospital.

Cincinnati

Marooned in Europe.—Drs. B. Knox Rachford, Joseph Ransohoff, John M. Withrow and J. Henry Schroeder are among the Cincinnati physicians who are held in Europe on account of war conditions.

Personal.—Dr. J. Stewart Hagen has been appointed city physician, with Drs. Harry M. Box and Joseph W. Hall as assistants. —Dr. Harry T. Summersgill has been chosen as superintendent of the University Hospital, San Francisco.

OKLAHOMA

Personal.—Dr. George A. Boyle, Enid, is taking a trip to Cincinnati, Battle Creek and Chicago, to get new ideas on hospital construction. —Dr. Edward N. McKee, Enid, is taking an automobile trip to Chicago.

Home from Europe.—Prof. Edwin De Barr, head of the department of chemistry of the State University, Norman, has returned from Germany. —Dr. and Mrs. Antonio D. Young, and Dr. and Mrs. Robert M. Howard, Oklahoma City, and Dr. and Mrs. Walter E. Wright, Tulsa, have returned from abroad.

OREGON

New Officers.—Eastern Oregon Medical Society at Pendleton: president, Dr. George W. Tape, Hot Lake; secretary-treasurer, Dr. Thomas M. Henderson, Pendleton (reelected).

Personal.—Dr. Orla B. Miles, Salem, has succeeded Dr. J. Olin Van Winkle, Salem, as health officer of Marion County. —Dr. Frank E. Boyden, Pendleton, has returned from Europe.

Alumni Meeting.—At the annual meeting of the Alumni Association of the Medical Department of the University of Oregon, held in Portland, more than one hundred were present. The program of the three-day meeting consisted of clinics, the presentation of papers, symposiums and post-graduate works.

PENNSYLVANIA

Home from Europe.—Drs. Arthur H. Bernstein and James F. Saltry, Scranton, and Dr. William J. Winters, Shenandoah.

Fire in Nurses' Home.—Fire destroyed the nurses' home of the Pittsburgh Hospital, August 19, causing damage of about \$5,000.

Personal.—Dr. John R. Stein, Shenandoah, is reported to be seriously ill in the State Hospital, Fountain Springs. —Dr. Nathaniel C. E. Guth has taken charge of the Laby clinic at Allentown.

Magazine for Anti-Tuberculosis League.—The initial number of the *Out o'Door Magazine*, the official publication of the Anti-Tuberculosis League, has just appeared at Oil City. It contains interesting information regarding Bon Air and Grand View, the two sanatoriums of the organization.

Emergency Hospital Plan.—Dr. George J. Van Vechten, superintendent of the Scranton Bureau of Health, and the mayor of the city, are discussing plans for buildings to be erected at the State Emergency Hospital. Of the \$25,000 appropriated by the council last year for this purpose, \$7,500 has been expended for a tract of 5 acres on the East Mountain and the balance is to be expended in constructing buildings, laying out roads, clearing underbrush and fencing the property. There is already a nine-room house on the site and it is proposed to erect an administration building, one building for the exclusive use of small-pox cases, and two bungalows, each containing three private rooms, and a ward building with accommodations for from eight to sixteen patients.

Philadelphia

New Hospital Chartered.—A charter authorizing the establishment of a new hospital for the study and treatment of diseases of the digestive system was granted in common pleas court by Judge Ferguson, August 28.

Hospital Corner-Stone Laid.—The corner-stone of the new wing of the American Oncologic Hospital at Thirty-Third

and Powelton Avenue, was laid with appropriate ceremonies on August 28. Addresses were made by the president and secretary of the board of officers.

Personal.—Dr. W. H. F. Addison, assistant professor of histology and embryology at the University of Pennsylvania, has made his way to Holland and will return in September. —Dr. Edward Ledholtz, assistant professor of physiology at the University, who has been working at the University of Bonn, has not been heard from. —Dr. Henry Lowenburg has returned from abroad.

Funds Needed for the Consumptive Hospital.—On August 23 an appeal for funds to carry on the work for the Home for Consumptives at Chestnut Hill was sent out by the Philadelphia Protestant Mission. This institution, which has at present seventy-nine patients, is directed by the mission and is supported almost entirely by voluntary contributions, and the officials have unpaid bills on hands amounting to \$5,000.

SOUTH CAROLINA

Greenville Physicians Abroad.—Drs. R. E. Houston, Ernest W. Carpenter, Thomas T. and Curran B. Earl are detained in Europe by war conditions.

New Officers.—The Second District Medical Association at Bamberg: president, J. J. Cleckley, Bamberg; secretary-treasurer, Dr. Vance W. Brabham, Cope.

Antityphoid Inoculation.—Dr. Asbury F. Coward of the State Board of Health reports that more than 10,000 antityphoid inoculations were made in the state during July.

Tuberculosis Camp Open.—The Tuberculosis Camp established by the Associated Charities of Columbia at Ridgewood has been opened. There are at present four tents and more will be added from time to time as may be required.

Professional Building.—A two-story and basement brick building is being erected on Main Street, Greenville, which will be used by physicians and dentists. The building is to be known as the Professional Building.

Personal.—Dr. James H. McIntosh, Columbia, was shot and seriously wounded, July 22. A reward of \$5,000 for the arrest and conviction of the man who shot Dr. McIntosh has been offered by J. W. Norwood, a banker of Greenville. —Dr. Joseph E. W. Haile, Columbia, charged with malpractice, was exonerated when the case was brought to trial.

Gift to Georgia College.—Dr. William J. Young, Barnwell, has given \$25,000 to the Medical Department of the University of Georgia, Augusta, to be known as the William J. Young Library fund, and to be devoted to the improvement and development of the library of the college. The conditions of the gift provide that the principal be invested and that the income shall be used by the board of directors of the medical department for purchasing and binding such books, magazines and periodicals as may be designated by the dean.

SOUTH DAKOTA

Personal.—Dr. C. A. Homan, Aberdeen, has returned from abroad. —Dr. Burtis T. Green, Brookings, is reported to be detained in Europe. —Dr. Henry E. Binger, Clark, has accepted a fellowship in the University of Minnesota and will move to Minneapolis. —Dr. Leslie G. Hill, Watertown, has resigned after eight years' service as a member of the South Dakota State Board of Health and Medical Examiners.

WASHINGTON

Home from Europe.—Dr. Saxe W. Mowers, Tacoma, and Walter E. Keehl, Cle Elum, have returned from Europe.

New Officers.—Washington Association for Relief and Prevention of Tuberculosis at Tacoma: president, Dr. Christen Quevli, Tacoma; vice-president, Dr. Wilson R. Johnston, Spokane; secretary, Prof. John Weinzirl, Seattle, all reelected. —North End Medical Society at Seattle: president, Dr. Charles A. Warhanik; secretary-treasurer, Dr. Frederick A. Slyfield.

Personal.—Dr. Joseph M. Audic, Spokane, has started for France, where he will join his regiment, the Eleventh Infantry. —Dr. Harry A. Shaw, Seattle, has been elected physician of the Police Relief Association. —Dr. Frank C. Robinson has succeeded Dr. Lawrence R. Quilliam as physician of the State Prison, Walla Walla. —Dr. Elwin Brown, Tacoma, will open a sanatorium for liquor and drug addiction at Lake Bay this fall.

WISCONSIN

New Officers.—First District Medical Society at Hartland, August 7: president, Dr. Willibald J. Wehle, West Bend; secretary-treasurer, Samuel B. Ackley, Oconomowoc.

European Travelers.—Drs. F. Gregory Connell and Neil Andrews, Jr., Oshkosh, and W. Weber Kelley, Green Bay, have returned from abroad. —Dr. Adolph Roos, Oshkosh, with his wife and daughter, is believed to be in Vienna.

GENERAL

Conference on Tuberculosis.—The Mississippi Valley Conference on Tuberculosis will be held at St. Louis, October 6 to 8.

Osler Urges Typhoid Vaccination.—Sir William Osler has sent a letter to the London *Times*, urging the emphatic necessity of enforcing antityphoid vaccination in the British army.

Missouri Valley Physicians to Meet.—The twenty-seventh annual meeting of the Medical Society of the Missouri Valley will be held at Colfax, Iowa, September 17 to 19. The Hotel Colfax will be the headquarters and meeting place, and on September 19 a clinical session will be held at Des Moines. Dr. Flavel B. Tiffany, Kansas City, is president, and Charles Wood Fassett, St. Joseph, Mo., is secretary of the society.

Sioux Valley Physicians Meet.—At the annual meeting of the Sioux Valley Association in Sioux Falls, S. Dak., the following officers were elected: president, Dr. Robert Evans, Fort Dodge, Iowa; vice-presidents, Drs. Julius A. Hohf, Yankton, S. Dak., and Charles L. Sherman, Luverne, Minn.; secretary, Dr. George S. Browning, Sioux City, Iowa, and treasurer, Dr. Walter R. Brock, Sheldon, Iowa.

Bequests and Donations.—The following bequests and donations have recently been announced:

Boston University School of Medicine, \$5,000 by the will of Dr. Alema J. Flint.
To equip a ward in memory of his brother, William H. Thorndike, \$200,000, by the will of George L. Thorndike, East Boston.
To equip a ward in a hospital in Philadelphia, devoted to contagious diseases, \$25,000, by the will of James M. Holt.
Aultman Memorial Hospital, Canton, Ohio, a lot for the endowment fund and a second lot to be applied to the endowment fund after the death of Susan Palmer, by the will of Johnson Sherrick.
Mrs. J. Clark Stewart, a trust fund of \$35,000, by the will of Dr. J. Clark Stewart, Philadelphia.
Chester County (Pa.) Hospital, a donation of \$6,000 for the endowment of a ward, by Mr. and Mrs. Jackson A. Watt, Oxford.

The New Orleans Plague Situation.—Since the report made last week, two cases of human bubonic plague bacteriologically confirmed have been found in New Orleans. Case 21, Mary Jones, colored, female, widow, aged 84, housewife; residence 1734 Felicity Street; sickened August 26 with left femoral bubo; diagnosis made positive August 28. Case 22, Elmore H. Read, male, aged 30; nativity United States; white; residence 4415 Carondelet Street; sickened August 26; suspicious August 27; positive diagnosis made August 28; right femoral bubo. Cases 65 to 74 of rodent plague have been reported up to August 29. During the week ended August 22, the Outgoing Quarantine Department fumigated 98 vessels with sulphur and 18 vessels with carbon monoxide; burned 5,981 pounds of sulphur; inspected 19,912 tons of outgoing freight and issued 29 clean and 3 foul bills of health. The Department of Overland Freight Inspection inspected 5,889 cars; ratproofed 1,280 cars; condemned 10 cars and killed one rodent in a car. The Department of Field Operations trapped 9,630 rats; fumigated 4 premises; disinfected 92 premises; inspected 3,482 premises; placed 88,316 poisons; served 1,450 notices; made 675 abatements and inspected 117 dead. The Department of Laboratory Operations received 9,329 rodents and examined 7,850; of these 15 were suspicious and in 9 the rats were found infected. Thus far 3 necropsies have been made; 54,885 rodents have been trapped and 51,985 rodents have been examined. —It is reported by the New Orleans papers that the State Board of Health has decided that it cannot add to its appropriation of \$10,000 already made and expended in this campaign, and the governor is said to have announced that the state could not provide anything from the \$150,000 authorized by the legislature to be borrowed for the fight. It is understood, however, that notwithstanding this action, there will be no abatement of the work as mapped out. —At the outset of the campaign it was suggested by Surgeon-General Blue that the federal government and the city of New Orleans should each bear

two-fifths of the expense and the state one-fifth.—It is also reported that in the daily press that the seven plague patients in the North Rampart Street Isolation Hospital have practically recovered from the disease and will be discharged within a week.

CANADA

Canadian Army Medical Service.—There are about 350 medical officers in the Canadian militia and many of these will probably be called on for active duty in the field.

Public Health Meeting Canceled.—Owing to the unsettled conditions due to the war in Europe, it has been decided to cancel the meeting of the Canadian Public Health Association, which was to have been held in Fort William and Port Arthur, Ont., September 10 to 13.

New Health Officers' Association.—The municipal officers of health in the counties of Haldimand, Wentworth, Norfolk, Brant, in the province of Ontario, have organized an association and elected Dr. Thomas A. Bertram, Dundas, president, and Dr. James Roberts, Hamilton, secretary.

Sanatorium Work Suspended.—The Anti-Tuberculosis League of Saskatchewan has had to suspend work on a new sanatorium for tuberculosis being built at Fort Qu'Appelle. The total cost of the building was to be in the neighborhood of \$225,000 and of this amount \$150,000 has been spent. Those who were to find the balance have been unable to find the funds, hence the suspension of the work.

The Academy of Medicine and the War.—A special meeting of the Academy of Medicine, Toronto, was held August 27. One thousand dollars was voted from the funds of the academy to the Toronto Patriotic Fund to provide for the dependents of those who had gone to the front. It was also unanimously decided to undertake without charge, the professional care of the needy dependents of the volunteers. A committee of past presidents will arrange to look after the practices of the professional members who have departed with their regiments.

Personal.—Drs. Andrew R. Gordon, Toronto, and John M. Elder, Montreal, presented the addresses in medicine and surgery, respectively, at the annual meeting of the Saskatchewan Medical Association of Saskatoon, August 18-20.—Mr. Irving Howard Cameron, professor of surgery in the University of Toronto, has offered his services to the British Government, it is understood in connection with base hospital work.—Dr. Wallace A. Scott, Toronto, will be in charge of the Army Medical Service of the Toronto branch of the first Canadian contingent.—Hon. Dr. Bceand, a former member of the Laurier Government, Canada, early entered the Belgian service.—The assistant superintendent of the Toronto General Hospital, Dr. Alfred K. Haywood, is off to the front with the Queen's Own Rifles of Toronto.—Dr. Duncan N. MacLennan, Toronto, has returned from a trip to the Mediterranean.—Dr. Richard A. Reeve, professor of ophthalmology in the University of Toronto, has secured passage and is returning from England.

LONDON LETTER

LONDON, Aug. 14, 1914.

CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA

(Concluded from page 794)

Cancer of the Breast

Dr. W. L. Rodman, Philadelphia, opened a discussion on this subject. He said that chronic fibrous hyperplasia with cysts, the result of abnormal involution of the breast, is often mistaken for cancer. It generally occurs about the menopause but may be seen in patients from 20 to 30. It differs from cancer in that it is frequently bilateral and painful (early cancer is not painful). The pain is increased before each period, and the superficial veins become enlarged. Cancer, unlike benign neoplasms, soon becomes fixed, but the fixation at first is so slight as to be detectable only by careful examination. Dimpling of the skin, however slight, indicates cancer unless chronic mastitis had previously existed. Too much attention has been paid to dimpling of the nipple. It does not occur in more than 52 per cent. of carcinomas, and is present in 5 per cent. of benign growths and more often in abnormal involution. There is the difference, however, that in cancer the nipple, as well as retracted, is infiltrated, fixed and immobile, whereas in benign growths the nipple is mobile. We should get away from the old teaching that cancer is a disease after 40; 20 per cent. occur between 30 and 40. The differentiation of benign from malignant cysts is even more difficult than in the case of

solid tumors. Thick granular discharge from the nipple is suggestive of carcinoma; in abnormal involution the fluid is fairly sanguineous. Pure blood nearly always means a papillary cystadenoma. In at least 25 per cent. of the cases a skilled diagnostician will fail to make a correct diagnosis. The proper way is exploratory incision. Benign growths are convex on section, pink or pinkish-white; malignant growths are usually concave and creak under the knife and have a gray tint. Though the expert may be able to distinguish benign from malignant growths by inspection, the only safe way is a frozen section at the time of operation.

Mr. Sampson Handley differed from Dr. Rodman in a few small points. Cancer of the breast is not always a fixed tumor and the skin does not always dimple over it. He described his now well-known theory of dissemination by lymphatic permeation. He said that secondary deposits rarely occur at a greater distance than 24 inches from the primary growth.

Intestinal Stasis

Sir Berkeley Moynihan opened a discussion on this subject. The theory of intestinal stasis, he said, asserts that at definite points along the intestinal canal certain membranes, veils or webs are frequently found, which delay the passage of the contents, producing intoxication, which directly causes some diseases and encourages others. He admitted that these membranes are frequently present but believes them to be congenital. As long ago as 1899 he described them in fetuses. Jackson's membrane is commonly congenital, but the bands found at the hepatic and splenic flexures are not seldom congenital. He agreed with Lane's view as to their origin, but he doubted that the bands are responsible for intestinal delay, for the intestine is not hypertrophied. Delay undoubtedly occurs in the typical case of intestinal intoxication, not from obstruction but from inability of the enfeebled intestine to empty itself. The early cases can be greatly helped by massage and paraffin. If operation becomes necessary the lower end of the ileum, cecum and ascending colon are the parts best removed. He condemned ileosigmoidostomy as it nearly always leads to regurgitation back into the colon. The surgeon exceeds his duty if he deals with anything beyond demonstrable lesions. He admitted that he had seen cases of rheumatoid arthritis improved beyond expectation by operative abdominal measures; but it should be remembered that drainage of an infected gall-bladder or removal of a diseased appendix will cure some cases of this disease. Moreover, most of these cases are not benefited by operations for intestinal stasis. He demurred to the wide range of diseases said to be curable by operations for intestinal stasis.

Sir Bertrand Dawson admitted that the successes of colectomy are very striking, but side by side there are great failures. The best results are obtained when the large bowel is definitely diseased. He demurred to the doctrine that the colon is a useless organ just as well removed as left. The mortality of colectomy is considerable, and it is often followed by frequent actions of the bowels at irregular intervals.

Sir Arbuthnot Lane said that in view of the lateness of the hour all he would say was that he was content that his views should be judged by the results.

On behalf of the American surgeons a committee, Drs. Leonard Freeman, Floyd W. McRae and William L. Rodman, drew up resolutions of thanks for the hospitality shown by London surgeons and hospitals to the Clinical Congress of Surgeons of North America.

The Annual Meeting of the British Medical Association

The eighty-second annual meeting of the British Medical Association was held at Aberdeen, unfortunately at the same time as the Clinical Congress of the Surgeons of North America in London. The president, Sir Alexander Ogston, delivered an address on the "Making of a Scottish Medical School." He traced the history of the district from the earliest times, when it was inhabited by the Celts. Later it was invaded by Scandinavians, Teutons and Saxons, who were more maritime races. Their physical differences from the Celts could still be observed. He estimated that 7 per cent. of the population were still of a tolerably pure Celtic type. The newcomers gradually fused with and no doubt in some cases dispossessed the Celts. The university was founded in 1494, a bull for this purpose being granted to Bishop Elphinstone by Pope Alexander VI. The first professor of medicine was James Cuming, who was appointed in 1503.

THE ESTABLISHMENT OF A DEFENSE FUND

At the meeting of the representative body there was an echo of the controversy in connection with the insurance act. A discussion took place on a proposal to establish a special fund for the defense of professional interests chiefly in view of future developments in national insurance, which might be injurious to panel doctors. The object is to make opposition effective by guaranteeing support to those members who otherwise could not afford to resist. The proposal was carried by a large majority. A debate then took place as to whether the fund should be administered by a trust or a trade union. The chief reason in favor of a trade union was that the funds would be inviolable against an action for damages. Several objections were raised. It was pointed out that the case of physicians is widely different from that of railway men or miners. The cohesion of the latter is not possible among physicians who work apart and often in antagonism to one another and not under a common employer. Although a majority report of the council favored the establishment of a trade union, it was decided that the fund should be administered by a trust.

MALINGERING

Sir John Collie, who in consequence of extensive experience with claims for disablement has become an authority on malingering, said that frequently the happening of an accident so perverted the outlook of the victim that he persistently dwelt on and exaggerated all his unusual sensations and in process of time he genuinely believed that he was not fit to work. While labor had become more and more monotonous than it used to be, the stimulus to return to work was much less. Every recollection of an accident brought a further injury to the nervous system and the mind. When confronted with these difficult cases the first and all-important step was to make as certain as possible that no organic disease existed. This was not easy, because certain organic diseases in the incipient stages closely resembled hysteria and neurasthenia. It was often a nice point how much was due to the accident and how much to the patient's own unconscious mental processes. In a railway accident passengers who happened to be asleep or tipsy did not suffer nearly so much subsequently from mental symptoms. It was unfair to insurance companies that physical disabilities should cause incapacity of work for four or six months simply because the patient had not been taken in hand from the mental point of view. He concluded that many of the cases were functional nerve cases and there was less deliberate fraud than might be supposed.

CONFIDENTIAL DEATH CERTIFICATES

Sir Victor Horsley spoke of the need of improvement of the nation's statistics, the importance of which, from the point of view of public health, had, he said, never been realized by the statesmen responsible for preparing them. The association should produce a real "nomenclature of diseases," from which the old loose names, which led to so much inaccurate certification, were expunged. The English and the international lists of diseases were chaotic nonsense. There should be direct certification of the cause of death, and the certificate of death and the cause of death should be separate documents. Among the reforms he advocated was the certification of stillbirths, which would secure for the nation statistics on a subject on which it had none, namely, antenatal conditions, which were to a large extent responsible for infant mortality.

(To be continued)

BERLIN LETTER [Delayed in Transmission]

Personal
BERLIN, July 31, 1914.
Dr. Abel has accepted a call as director of the Hygienic Institute at Jena.
The Strassburg anatomist and anthropologist, Gustav Schwalbe, celebrated his seventieth birthday August 1. He joined the faculty of Freiburg in 1871, but in the same year went to Leipsic as professor extraordinary and in 1873 was called to Jena as regular professor of anatomy as the successor of Gegenbaur. In 1881 he went to Königsberg and two years later settled at Strassburg as the successor of Waldeyer. Among Schwalbe's works on anatomy are especially to be noted his study of the circumvallate papillae discovered by him, and also his studies on the growth of bone and cartilage, on the lymph channels of the eye and on the topography of the brain. Of his anthropologic studies those on

the Neandertal skull, his method of measuring the skull and his investigation of the most ancient races of man are to be noted. Schwalbe has published two text-books on the anatomy of the nervous system and of the organs of sense, and he founded the *Zeitschrift für Morphologie und Anthropologie* and the *Anatomischer Jahresbericht*. Schwalbe resigns his position at the end of the summer semester.

Pathology and Therapy of Cancer

Two important addresses treating of the problem of cancer and its treatment were delivered a few days ago in the Berlin Surgical Society by von Hansemann, the pathologist, and Bier, the surgeon. Von Hansemann divided the history of cancer research into a number of periods.

HISTOLOGY OF CANCER

The first is the histologic morphologic period. This was the beginning of exact investigation by scientific methods. The anatomic structure of cancerous tumors was studied and a number of characters were learned which distinguish them from healthy tissues and from pathologic changes of other sorts. This has the enormous advantage in a practical way that one may operate early on the basis of an early diagnosis of cancer and thus often completely eradicate the malignant disease.

ETIOLOGY OF CANCER

Then followed the etiologic period which, in many places, was not distinguished by an equal scientific character as the first period. This period of investigation had an important result in the development of the irritation theory. This teaches that the origin of a cancerous tumor depends on some sort of irritation, but in such a way that irritants of various kinds may produce the same sort of tumor, or that irritants of the same sort in different individuals may produce different kinds of tumors. Thus we know that the irritation produced by the Roentgen rays may cause cancer. The fine experiments of Fibiger of Copenhagen have shown that such irritation may also be produced by parasites, not in the sense that parasites cause cancer in the same way as the comma bacillus causes cholera, but that the presence of the parasites produces an irritant that in one case may have no consequences; in another case a slight inflammation may be set up; in a third, a benign growth, and in the fourth a genuine cancer may develop.

EXPERIMENTAL CANCER RESEARCH

The third period is that of experimental investigation. On a single occasion it was found possible to transmit a genuine cancer from one rat to another. Then a tumor was found in mice with which experiments were conducted for years almost exclusively. As the work was carried on with great diligence and with abundant means, important scientific results were reached with reference to the biology of cells and to the conditions which favor and hinder the growth of man have been realized, for this tumor of the mouse differs in important respects from the cancer of man and the observations made on it cannot, as a rule, be transferred to human cancer. Just recently, for the first time, through the researches of Fibiger mentioned above, something can be hoped for from experimental investigation because in his experiments genuine cancer was induced.

TREATMENT OF CANCER

Lastly we come to the therapeutic period. As is well known, the therapeutic results which have been obtained with newly discovered remedies, partly by Wassermann, partly by Neuberg and Caspari, have all been achieved in mouse cancer, but so far the same treatment cannot be employed in human beings. The treatment by radium and the Roentgen rays does not stand in the same class. It is rather to be compared with surgical treatment inasmuch as it destroys the tumor but does not actually cure the disease. An actual curative remedy, like the salicylates in articular rheumatism, is known only in such diseases as those in which occasionally the patients recover without treatment. Hitherto, no case is known in which a genuine cancer became cured spontaneously. Von Hansemann emphasized this most decisively, and repeated it with marked energy in the discussion, saying that in all the cases that have been published as spontaneous cures, the disease either was not true cancer or only parts of the tumor receded and there was no general recovery. Consequently von Hansemann comes to the conclusion that it will never be possible to find a specific remedy for cancer.

ROENTGENOTHERAPY OF CANCER PLUS INJECTION OF BLOOD

Bier's address on this subject indicates that new hopes may be entertained. Some years ago, he made experiments with the blood of healthy animals. Lately he has resumed these in conjunction with roentgenotherapy and in a number of cases he has reached quite remarkable results, at least for the time being. He showed a patient who had been repeatedly operated on for cancer of the throat, and still the tumor had grown anew and of greater extent. The pictures which Bier showed from the time previous to the treatment made it clear to every one that the case was very severe. A deep radiation with the Roentgen rays was applied to the tumor, while at weekly intervals from 8 to 10 gm. of the blood of healthy hogs was injected. No trace of the cancerous tumor can be detected now in this patient. Bier did not venture to say how permanent the result would be or what would be the future fate of this patient and others treated in the same manner, and he would not state even his presumptions. An opinion on the favorable side is not possible until after some years.

EFFICACY OF ROENTGENOTHERAPY

Bumm's address, delivered in the Hufeland Society on the cure of deep-lying carcinoma by the Roentgen ray from the surface of the body, is also calculated like the statements of Bier to overthrow the pessimistic view of Hansemann in regard to the curability of cancer. Bumm regards his experiences as very favorable. With radio-active substances, a curative effect cannot be obtained at a greater depth than 2 or 3 cm. from the surface without injury to the neighboring tissues. But in the case of superficial cancerous growths, a quick and apparently permanent cure is obtained. In advanced cases in which infiltrations in the neighborhood of the primary focus have formed, a cure of the superficial cancerous growth is obtained, but under the cicatrix in the depths of the tissues the carcinoma continues to grow, and physicians who see the patient after six months or a year find a healed primary focus with fresh nodules in the deeper tissues. No success has been obtained by the attempt to act on the deeper lying parts by the use of larger doses of radio-active substances or by prolongation of the radiation. The use of the Roentgen rays produced better results as the Roentgen tubes furnish many thousand times the amount of radiant energy that is obtainable from the available quantity of radio-active substances, if the superficial tissues are protected from the intense caustic action and a sufficient action in the deeper parts is obtained without the danger of severe injury to the tissues. The cure of cancer is a question only of the quantity of rays which can be applied to the pathologic tissues. As the intensity of the radiation diminishes rapidly in proportion to the distance below the surface, only the hard rays can be used. Bumm is of the opinion that the Roentgen rays afford the remedy which alone is capable of checking the growth and thus securing a permanent cure of deep, advanced carcinoma.

Marriages

ALFRED L. FOWLER, M.D., Atlanta, Ga., to Miss Helen Achenbach of Roslyn Ranch near Rand, Colo., August 12.

CHARLES F. W. BOVE, M.D., Cumberland, Md., to Miss Cecelia H. Flaig, formerly of Catskill, N. Y., August 22.

HUGH ERSYTHE LORIMER, M.D., Oxford, Ohio, to Miss Sarah Florence Shaw of New Concord, Ohio, August 18.

ALEXANDER EDWIN MCCORNACK, M.D., Elgin, Ill., to Miss Josephine Jernstad of Ishpeming, Mich., August 26.

FREDERICK JOHNSON, M.D., Eau Claire, Wis., to Miss Augusta Lange of New Freedom, Wis., August 12.

ANNE EUNICE COCHRAN, M.D., Brooklyn, N. Y., and Mr. John Emmet Carey of New York City, August 8.

EDWIN VAN NOTE, M.D., Hamilton, Mo., to Mrs. C. M. Perry of Pasadena, Cal., at Galena, Mo., July 9.

CALVIN BREWSTER COULTER, M.D., New York City, to Miss Grace Dickey of Iroquois, S. Dak., August 19.

MAURICE A. HANSON, M.D., to Miss Alice McCoy, both of Osage, Iowa, at Charles City, Iowa, August 13.

WILLIAM S. HECTOR, M.D., to Miss Edna E. Dickens, both of Chicago, at Crown Point, Ind., August 22.

HERBERT ROWELL STOLZ, M.D., to Miss Margaret Post, both of San Francisco, August 8.

Deaths

HASKETT DERBY, M.D. Harvard University Medical School, 1858; a Fellow of the American Medical Association; known throughout the United States as an ophthalmologist; one of the founders and once president of the American Ophthalmological Society; for more than forty years a practitioner of Boston; a medical officer of the Army during the Civil War; for thirty years consulting surgeon to the Massachusetts Charitable Eye and Ear Infirmary; founder of the eye clinic in the Carney Hospital, Boston, in 1887; for many years lecturer on ophthalmology at Harvard Medical School and trustee of the Public Library and of the Children's Institutions Department of Boston; died at his home in Falmouth Foreside, Maine, August 21, aged 79.

MAYNARD GOODING BURGESS, M.D. College of Physicians and Surgeons in the City of New York, 1898; a veteran of the Spanish-American War during which he served in Cuba as a medical officer on the staff of General Wheeler, being discharged on account of permanent disability; died at his home in Herkimer, N. Y., August 14, from the effects of a gunshot wound of the head, believed to have been self-inflicted with suicidal intent while despondent on account of ill health, aged 38.

CARRINGTON MACFARLANE, M.D. College of Physicians and Surgeons in the city of New York, 1861; assistant surgeon of the Eighty-First and One Hundred and Fifteenth New York Volunteer Infantry, during the Civil War; one of the organizers of the Oswego City Hospital and for many years a member of the staff and board of directors; prominent also in commercial enterprises in Oswego, N. Y.; died at his home in that city, August 12, aged 77.

EDWIN PYNCHON, M.D. Eclectic Medical Institute, Cincinnati, 1873; Medical College of Ohio, Cincinnati, 1876; a Fellow of the American Medical Association and a member of the American Academy of Ophthalmology and Otolaryngology; and professor of rhinology, laryngology and otology in the Chicago Eye, Ear, Nose and Throat College; died at his home in Chicago, August 28, from uremia, aged 67.

ROBERT P. MARSHALL, M.D. Miami Medical College, Cincinnati, Ohio, 1873; a member of the Medical Society of the State of Pennsylvania; president of the Armstrong County (Pa.) Medical Association and one of the founders of the Kittanning, Pa., Fair Association; died at his home in Kittanning, August 19, from cerebral hemorrhage, aged 66.

ALBERT MERRITT COOK, M.D. University of Buffalo, N. Y., 1881; Bellevue Hospital Medical College, 1883; for twenty-five years a practitioner of Newcastle, Pa., and a member of the staff of the Shenango Valley Hospital; died at his home in Pasadena, Cal., August 16, aged 59.

JAMES LUTHER VAIL, M.D. Eclectic Medical Institute, Cincinnati, 1899; of Little Rock, Ark.; aged 45; died in St. Vincent's Infirmary, Little Rock, August 17, from the effects of injuries received in a collision between his automobile and another motor car.

WILMOT FREDERICK MILLER, M.D. University of Michigan, Ann Arbor, 1887; of Milwaukee; a Fellow of the American Medical Association, and a specialist in nervous diseases; died in St. Mary's Hospital, Milwaukee, August 14, from diabetes, aged 53.

CHARLES BETTS, M.D. University of Wooster, Cleveland, Ohio, 1890; a Fellow of the American Medical Association; proprietor and superintendent of the Jefferson Hospital, Toledo, Ohio; died at Beulah, Mich., August 16, from heart disease, aged 49.

A. N. PERKINS, M.D. New Orleans School of Medicine, 1858; for many years a practitioner of South Texas, and for eighteen years State Quarantine Officer at Sabine Pass, Tex.; died at the home of his daughter in Houston, Tex., August 13, aged 89.

JAMES ROBIE WOOD, M.D. Bellevue Hospital Medical College, 1867; of New Brighton, N. Y.; a Confederate veteran; while returning from a visit to his daughter in the Philippine Islands; died at sea on the U. S. A. Transport *Logan*, August 9, aged 76.

JOSEPH F. ROBERTSON, M.D. Columbus, Ohio, Medical College, 1881; a Fellow of the American Medical Association, and a practitioner of Steubenville, Ohio, for thirty-five years; died at his home in that city, August 17, from septicemia, aged 62.

Cyrus Ernest Hoover, M.D. Emsworth Medical College, St. Joseph, Mo., 1880; a Fellow of the American Medical Association; and a member of the Medical Society of the Missouri Valley; local surgeon at Hamburg, Iowa, for the Burlington System; died at his home in Hamburg, August 21, aged 56.

William Edward Dillingham, M.D. Denver and Gross Medical College, Denver, Colo., 1903; of Mead, Colo.; while crossing the Mummy Mountains into Estes Park, Colo., August 19, was struck by lightning and instantly killed, aged 35.

William Henry Harrison Gable, M.D. Rush Medical College, 1879; for many years a practitioner of Osage, Iowa; and for four years state physician of the Maccabees; died at the home of his daughter in Boise City, Idaho, August 14, aged 73.

Charles H. Bacon, M.D. Northwestern University Medical School (Chicago Medical College), 1862; surgeon of volunteers during the Civil War; a resident of Lockport, Ill., since 1852; died at his home in that city, August 20, aged 80.

Charles Moman Johnston, M.D. Rush Medical College, 1914; of Idaho Falls, Idaho; formerly assistant in pathology at the Michael Reese Hospital, Chicago; died in that institution, August 15, from typhoid fever, aged 29.

Westley Rogers Wales, M.D. Jefferson Medical College, 1891; a member of the board of health of Cape May, N. J., and formerly physician of Atlantic County, N. J.; died in a sanatorium in Atlantic City, August 11, aged 45.

Frederick F. Chaffee, M.D. New York University, New York City, 1877; a member of the Vermont State Medical Society and Illinois State Medical Society; died at his home in Chicago, August 17, from nephritis, aged 59.

Charley Marion Cunningham, M.D. Starling-Ohio Medical College, Columbus, Ohio, 1909; formerly a practitioner of West Mansfield, Ohio; died in his apartment in Rasacca, Ohio, August 14, from heart disease, aged 32.

Daniel Campbell Rose, M.D. Harvard Medical School, 1869; for thirty-six years town and county health physician of Stoughton and Norfolk County, Mass.; died at his home in Stoughton, August 13, aged 76.

Leonard T. Whaley, M.D. University of Louisville, Ky., 1912; of Winslow, Ind.; was burned to death under his overturned automobile, August 13, while on his way home from the Huntingburg fair; aged 28.

Andrew C. Sheldon, M.D. Cleveland University of Medicine and Surgery, 1876; formerly a practitioner of Des Moines, Iowa; died at his home in Salt Lake City, Utah, August 23, aged 73.

Benjamin Dorr Colby, M.D. Rush Medical College, 1884; a member of the Illinois State Medical Society; died at his home in Austin, Chicago, August 14, from cerebral hemorrhage, aged 64.

Alvin Snyder, M.D. Missouri Medical College, St. Louis, 1873; for forty years a practitioner of Seneca, Kan.; died at his home in that city, August 23, from cerebral hemorrhage, aged 67.

Elmore Ferdinand Arnold, M.D. New York University, New York City, 1885; for many years a practitioner of New York City; died at his home in Londonderry, Vt., August 13, aged 55.

Gwynne Page Harrison, M.D. University College of Medicine, Richmond, Va., 1901; of Blair, W. Va.; was struck by a Chesapeake and Ohio train, August 12, and instantly killed, aged 34.

The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION

DIGALEN OMITTED FROM N. N. R.

Report of the Council on Pharmacy and Chemistry

Digalen is a proprietary said to contain a soluble form (digitoxinum solubile Cloetta) of digitoxin, the chief active principle of digitalis. This preparation was accepted by the Council in 1909 for inclusion in New and Nonofficial Remedies. The Council had not at that time determined whether Digalen contained "soluble amorphous digitoxin," as claimed, or not. The product was accepted merely as a standardized soluble and fairly stable digitalis preparation.

After the acceptance of Digalen, the therapeutic claims made for it by the manufacturers increased in extravagance. Meanwhile, evidence was brought forward by various independent investigators which tended not only to show that these therapeutic claims were unfounded, but also to discredit the claim that Digalen contained a principle chemically identical with digitoxin. In view of the obscurity of the whole subject of the chemistry of the digitalis principles, the latter claim (that Digalen was a solution of "amorphous digitoxin") had been an academic issue at the time of the acceptance of the product. When, however, the manufacturers of Digalen sought to mislead physicians by increased and unwarranted therapeutic claims, the Council felt that investigation of the whole matter was imperatively demanded to decide whether or not Digalen should be retained in N. N. R.

The questions at issue were: (1) the presence in Digalen of "amorphous digitoxin"; (2) the constancy of composition and reliability of action of Digalen, and (3) the claim that it causes less gastric disturbance than digitoxin. No satisfactory proof has yet been offered that Digalen contains "amorphous digitoxin." The mass of evidence tends to show that Digalen is not constant in composition or reliable in action, and that, when given in doses corresponding in therapeutic activity, Digalen causes quite as much gastric disturbance as the official galenical preparations of digitalis.

The outcome of protracted negotiations between the Council and the Hoffmann-La Roche Chemical Works may be summed up as follows: 1. The manufacturers promise to hold in abeyance the claim regarding the presence of "amorphous digitoxin." 2. They refuse to concede the variable composition of Digalen. 3. They reassert the claim that Digalen is superior to other digitalis products with respect to liability to cause gastric irritation and consequent vomiting.

In view of the unsatisfactory character of the reply on the second and third points, the Council voted that Digalen be omitted from N. N. R. and that publication of the report on Digalen which appears below, be authorized, as well as of the two reports² (A and B) referred to therein.

W. A. PUCKNER, Secretary.

Referee's Report on Digalen

Because of persistent conflict with Rule 6 (unwarranted therapeutic claims) and Rule 1 (composition) it is recommended that Digalen be omitted from New and Nonofficial Remedies. Also that a copy of the report be sent to the manufacturers, and that publication of this report and the two previous reports submitted to the Council be authorized.

The nature of the problems involved necessitates a somewhat extended discussion of the subject.

Digalen (liquid) is said to contain 1 part of soluble amorphous digitoxin Cloetta in 1,000 parts of glycerin and

1. THE JOURNAL A. M. A., Sept. 11, 1909, p. 869.

2. These reports (A, first report on Digalen and B, examination of Digalen Tablets) will be published in the 1914 Annual Council Reports. A reprint of the entire matter dealing with the rejection of Digalen will be sent on receipt of a two-cent stamp.

1,600 parts of water with 7.5 per cent. of alcohol. One c.c. is said to contain 0.0003 gm. of the amorphous digitoxin.

Digalen was accepted by the Council⁷ and the following footnote was appended to the description in New and Non-official Remedies:

"The Council has not determined whether digalen contains 'soluble amorphous digitoxin' or not, but accepts it simply as a soluble digitalis preparation."

Tablets of Digalen were accepted by the Council as a dosage form of Digalen. Each tablet is said to represent 0.5 c.c. (eight minims) of Digalen (liquid).

One of the principal considerations which led the Council to accept Digalen was that it was regarded as affording a fairly constant and stable preparation of digitalis suitable for intravenous administration; if Digalen is not fairly stable and of fairly constant composition it has no obvious advantage over an active soluble digitalis preparation, such as digitalein.

The evidence now at hand seems to show: 1. Digalen is not of constant composition or activity. 2. The manufacturers, or their agents, continue to make misleading statements. 3. It is merely a solution of certain digitalis principles, probably of digitalein mainly, in impure form.

COMPOSITION

Cloetta⁴ prepared a soluble amorphous substance which he called "Digitoxinum solubile Cloetta," but no information concerning the method of preparation has been published.

Cloetta reported the result of an elementary analysis of his product which he compared to the analyses of digitoxin (crystalline) made by Schmiedeberg and by Kiliani, and stated that there could be no doubt concerning the chemical identity of the two substances.

Kiliani⁵ characterized as preposterous, Cloetta's claim that the active constituent of Digalen is chemically identical with digitoxin and stated that Digalen was merely an impure digitalein. Kiliani has recently reiterated the statement that the so-called "amorphous digitoxin" is not identical with Digitoxin⁶.

Cloetta's failure to publish his method of preparing Digalen places an additional burden of proof on him (or the manufacturers of Digalen), concerning the identity of the product, and in the face of Kiliani's denial of the correctness of Cloetta's contention we must have strong corroborative evidence of Cloetta's claim before we can accept it as being established.

The difficulties of dealing with the chemistry of digitalis are so well known that they hardly require further mention here, but under the circumstances Cloetta cannot be considered as being wholly unprejudiced, and, while the same might perhaps, be said of Kiliani, such evidence as can be deduced tends strongly to support Kiliani's view, and to disprove the contention of Cloetta.

There is much confusion regarding the names which have been applied to the various principles obtained from digitalis, and while it is undesirable that an established name should be given to a newly discovered principle, one might overlook this if no effort were made to associate the therapeutic actions of the two substances to an extent which the truth did not justify.

The Council at that time did not challenge the existence of "amorphous digitoxin" and made no attempt to establish the identity with digitoxin of the substance forming Digalen, the manufacturers of Digalen showing that Digalen and digitoxin were identical in their therapeutic actions were concerned, but the disadvantages of digitoxin. What a serious question when the acceptance of Digalen by the Council becomes a matter of great importance when the manufacturers mislead the physician by these

The evidence which lends support to the view that Digalen and digitoxin are wholly dissimilar may be summarized as follows: Digalen differs greatly in its physical properties from digitoxin and in certain of its physiologic actions, as the manufacturers themselves state, Digalen being amorphous, and soluble in water, while digitoxin is crystalline and insoluble in water. The manufacturers state that Digalen differs from digitoxin in certain of its physiologic actions, but the two substances do indeed, differ far more than they admit.

Cloetta and the manufacturers of Digalen lay especial stress on the claim that Digalen is cumulative to a far less extent than digitoxin, and that it has far less tendency to cause gastric disturbance than the latter. The first of these claims is true; the second is the very opposite of the truth, as we shall show.

We know nothing of the structure of any of the digitalis principles, and even though one were to admit (purely for the sake of argument) that Digalen and digitoxin were chemical isomers, that fact could not be taken to lend any support to the contention that the two substances were identical, in the face of the established fact that they differ physically and physiologically in nearly every particular, and agree only in that they both cause standstill of the heart in the same way—an action possessed also by so dissimilar a substance as barium.

The manufacturers of Digalen support the claim of the identity of their product with digitoxin by stating that "Digalen is a solution of the most active glucoside of digitalis." Of course, it is very generally admitted that digitoxin is the most active principle of digitalis, though there is some question concerning its glucosidal nature.

Digalen is in fact far less active than digitoxin, as has been shown by a number of independent observers* (Worth Hale, 1910; Hatcher and Brody, 1910; Neave, 1907; Miller, 1908; the referee; Weis, 1912).

The essential fact which appears from the investigation of Weis is that *Digalen did not behave like digitoxin in any case.*

Hale also found that Digalen gave atypical actions in which the effects on the central nervous system became prominent. The referee can corroborate these observations of Hale's on frogs, but the convulsive symptoms were prominent with some specimens of Digalen on mammals, though not with others, the more recent specimens of the preparation showing the action prominently.

The results of all these biologic tests, as well as of the physical tests made by Weis, certainly lend no support to the contention of Cloetta that the potent constituent of Digalen is identical with digitoxin, but, on the contrary, they show conclusively that the two substances differ widely in many essentials, and the continued claim of the manufacturers that the "amorphous digitoxin" said to be contained in Digalen is the same as digitoxin, or that it is the most active glucoside of digitalis, can be considered only as misleading, and therefore in conflict with the rules of the Council.

CONSTANCY OF COMPOSITION AND ACTIVITY

The manufacturers of Digalen continue to claim that it is of constant and uniform activity,⁷ and they imply this even when they do not state it in those words; for example, a substance cannot be considered reliable if it is variable in activity. "Digalen is Absolutely Reliable. It is standardized and consequently always uniform. It does not produce gastric disturbances."

That the foregoing is absolutely untrue can be shown abundantly. Hale¹⁵ found Digalen not to be uniformly stable; Weis¹⁴ found very different degrees of activity for Digalen in the liquid and tablet forms, the tablets being but one-third as active as the liquid, and the referee found

* Owing to lack of space a portion of the report is here omitted. A detailed discussion of these results is contained in the full report, contained in the reprint.

al examination of
Council Reports
ction of Digalen will

very great variations in the activity of different specimens of Digalen, one specimen being almost inert. The results obtained by Miller show that Digalen is sometimes very slightly active, or not at all so.

The foregoing citations show conclusively that Digalen is not of uniform activity. When reliability is claimed for Digalen in contrast to the known variability of digitalis, it must be considered as tantamount to the claim that Digalen is not subject to such variability and it must be held that the manufacturers make misleading statements when they assert that Digalen is absolutely reliable.

The manufacturers claim that Digalen does not produce gastric disturbances (see advertisement cited¹⁶).

It is quite true that when small doses of Digalen are used therapeutically it fails to produce gastric disturbances because it is of such slight activity, as previously stated, but when it is used in amounts which correspond in activity to such doses of the ordinary galenical preparations of digitalis as commonly cause nausea and vomiting it does cause gastric disturbances quite as readily as the latter.

Among the clinicians who have found that Digalen causes gastric disturbances may be cited: Veiel,¹⁶ Mueller,¹⁷ Eichhorst¹⁸ and Teichmann.¹⁹

Eggleston and Hatcher²⁰ compared the emetic and cardiac activity of Digalen and numerous other digitalis bodies and preparations and found that the emetic activity of Digalen was decidedly greater in proportion to its cardiac (or therapeutic) action than was that of digitalis or digitoxin.

In the absence of any evidence to controvert this clinical and experimental evidence, the continued claim that Digalen does not disturb the stomach must be looked on as deliberate misrepresentation.

MISLEADING THERAPEUTIC CLAIMS

The recommendation that Digalen be dismissed from N. N. R. is made with the full appreciation of the fact that the manufacturers of Digalen and their agents have repeatedly stated that they desired to comply with the rules of the Council, and that they have withdrawn several statements to which the Council has taken exception, but the fact remains that despite these reiterations the advertisements of Digalen continue to embody statements which the Council can only consider misleading.

The Council believes that the following advertisements constitute gross therapeutic exaggerations:

"Digalen a sheet anchor in pneumonia; a strong support to the heart in this deadliest of infectious diseases among adults. The prompt action of Digalen, by intravenous or intramuscular injection makes it possible to save lives which might be otherwise hopelessly lost. The best digitalis preparation which we have at the present time."²¹

"The digitalis for children. Because its dosage can be controlled. Endorsed by pediatricists everywhere."²²

"The myocarditis of Tuberculosis so frequently encountered, especially in the advanced stage of the disease, may be controlled with the aid of Digalen. The standard digitalis preparation."²³

"Digalen is Absolutely Reliable. It is standardized and consequently always uniform. It does not produce gastric disturbances."²⁴

Digalen is not a sheet anchor in pneumonia, for there is no drug deserving such a title. Digalen has no action which other digitalis preparations lack, and cannot save lives otherwise hopelessly lost. The dosage of Digalen cannot be controlled any better than that of other digitalis preparations, since its activity is variable. We cannot control the myocarditis of advanced tuberculosis by this, or any other means.

CLAIMED SUPERIORITY

Various digitalis principles, including digitoxin, digitalin (true) and digitalein, have been known for many years. Therapeutically they have been found wanting and there

appears to be no basis for the continued claim that Digalen has any superiority over these several digitalis principles. On the contrary, the evidence is accumulating that Digalen has no advantage in any particular over a solution of digitalein, and misleading claims of the manufacturers and their agents certainly interfere with the formation of that calm and unbiased opinion on the part of the general practitioner, which, when applied to the non-proprietary digitalis principles has caused them to fall into disuse.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

WATER-GLASS IN THE PRESERVATION OF EGGS

To the Editor.—In THE JOURNAL, Aug. 29, 1914, p. 796, C. W. L., Denver, asks for the comparative and practical value of water-glass in the preservation of eggs. During August last year I put down about twelve dozen eggs in a solution of water-glass, one part to ten parts of water. The eggs were used during the winter and by some means half a dozen were left in the jar until this August, when I discovered them on making preparations to put down more. They were in a perfect state of preservation, having remained in the solution twelve months. The water should be sterilized and the eggs strictly fresh when put down, and I doubt if there is any limit to the time they will remain fresh.

B. F. METCALFE, M.D., Greenville, Ohio.

VALUE OF VON PIRQUET REACTION IN ADULTS—RELIABILITY OF BASS-WATKINS TEST

To the Editor.—1. When the von Pirquet reaction for tuberculosis is positively positive in an adult female, is that reaction pathognomonic of tuberculosis either active or latent?

2. Is the Bass-Watkins test for typhoid fever as reliable as the old Widal reaction?

S. W. DOUGLAS, M.D., Eudora, Ark.

ANSWER.—1. A positive result from the von Pirquet reaction indicates the presence of a tuberculous focus but does not distinguish between active and latent tuberculosis. This reaction is given by the majority of adults, and hence is of little value as a test in adults.

2. Yes.

ALCOHOL IN MILK AND URINE

To the Editor.—1. Please give a simple qualitative and quantitative test for the presence of alcohol in milk.

2. What is the reliability and specificity of Anstie's test for alcohol in urine?

R. K.

ANSWER.—1. Probably the best method is to distil the milk, then after adding sodium hydroxide to the distillate, to redistil and test the second distillate obtained for alcohol according to established tests such as the iodoform test or benzoyl-ethyl ester test, etc. It is asserted that the method of E. de Stoecklin (Compt. rend., Acad. d. sc., 1910, cl. 43; abstr., Chemical Abstracts, 1910, iv, 886) will detect alcohol in 4 drops of a solution of a strength of 1 part alcohol in 10,000. For the quantitative test the specific gravity of the distillate obtained quantitatively as described above should be determined and the percentage of alcohol in a known amount of milk calculated therefrom (See Bull. 107, Bureau of Chemistry, U. S. Dept. of Agric.).

2. We have no definite information regarding the reliability and specificity of Anstie's reaction. Merck's Report for 1900, p. 112, states that the emerald green color signifies the presence of alcohol in toxic quantities. In 1877 F. C. Hewett (Proc. Am. Pharm. Assn., 1877, xxv, 275) called attention to "the fallacy of Anstie's bichromate of potassium test for alcohol in urine, unless the latter be first distilled, the fallacy consisting in the reduction into the green oxid, not by alcohol singly, but by some agent present in the urine of persons who are total abstainers from alcohol. If the test be applied to the distillate in case of the alcohol having been taken in sufficient quantity to permit of its excretion in an unchanged form, the test will hold good, but not otherwise."

BLOOD DETERMINATION OF VARIETIES OF MAN

To the Editor.—Is there any known and positive method of determining whether blood is that of a white person or of a negro?

E. C. DUNNING, M.D., Cassopolis, Mich.

ANSWER.—No.

Book Notices

DIE KRANKHEITEN DES NEUGEBORENEEN. Von Dr. August Ritter von Reuss, Assistant an der Universitäts-Kinderklinik. Spezieller Teil, Enzyklopaedie der klinischen Medizin. Herausgegeben von L. Langstein, C. von Noorden and others. Paper. Price, 22 marks. Pp. 550, with 90 illustrations. Berlin: Julius Springer, 1914.

The thoroughness of this book, its detailed references to the literature, and its mass of detailed information regarding all of the unusual conditions of the new-born make it a splendid reference book. The chapter on the feeding of the new-born is especially good in its recital of the many difficulties that stand in the way of successful nursing and the best way to overcome them. The chapter on breast injuries and diseases of the alimentary and respiratory tracts is very complete. The same can be said of practically all of the other chapters. All the way through one sees the work of an author who has mastered his subject and presented it in a pleasing objective way. The illustrations greatly enhance the value of the book in that they show at a glance unusual conditions which one can understand much more easily by an illustration than by a long description. The book can be very highly recommended to all interested.

BEDSIDE HEMATOLOGY. An Introduction to the Clinical Study of the So-Called Blood Diseases and of Allied Disorders. By Gordon R. Ward, M.D. Cloth. Price, \$3.50 net. Pp. 394, with 42 illustrations. Philadelphia: W. B. Saunders Company, 1914.

Two admirable qualities characterize this work and form a reason for recommending it highly. The first is its practical character. The work deals with clinical relations and facts and as little as possible with questions of pathology. No time is wasted in the description of unnecessary technic for examinations; indeed, the space given to the examination of blood appears at first to be meager, but the reader will find sufficient details for the practical processes. The greater part of the work is devoted to the description of the different forms of disease of the blood-making organs, and incidentally to the changes in the circulating blood. The second point of advantage is the systematic classification. In an introductory chapter the author discusses the question of classification, and while admitting that his scheme is open to various objections and to the charge of inconsistency, he develops an arrangement which is of great aid to the reader. The first disease that is discussed is lymphemia. The symptomatology of this disease is thoroughly worked out and affords a basis for subsequent comparison with the other forms of blood diseases. In reference to etiology, a possible gastro-intestinal origin is suggested, and this is more distinctly recognized with reference to the general forms of anemia. Addisonian anemia or pernicious anemia is said to be almost certainly due to the activities of a micro-organism. The author says: "The exciting cause is the growth and development of the causal organism. There is evidence to suggest this is a denizen of the intestinal tract, perhaps of the whole alimentary canal." The book is well illustrated with numerous figures and especially two colored plates.

ROTH'S KLINISCHE TERMINOLOGIE. Zusammenstellung der in der Medizin gebräuchlichen technischen Ausdrücke mit Erklärung ihrer Bedeutung und Abteilung. Bearbeitet von Dr. E. Oberndorfer. Eighth Edition. Cloth. Price, 12 marks. Pp. 484. Leipzig: Georg Thieme, 1914.

This is a new and greatly modified edition of a work little known to American physicians. Naturally a dictionary in a foreign language will be of little service to the English-speaking physician even when it includes, as does the present work, a good collection of the medical terms of German origin. The work included at first only such terms as were used in the field of clinical medicine, terms relating to materia medica, chemistry and allied topics being omitted. These defects have been remedied in the present edition with the result of increasing the size of the book by about half. Terms derived from or current in other languages than German are defined, so that the usefulness of the work is materi-

ally increased. This work may be confidently recommended to German readers, and we can only second the hope expressed by the reviser that as Roth's "Clinical Terminology" has maintained its usefulness for thirty-six years, the work in its new form will find many friends.

LEITFADEN DER SÄUGLINGSPEDIATRIE FÜR STUDIRENDE UND ARZTE. Von Dr. Walter Birk, Privatdozenten für Kinderheilkunde an der Universität Kiel. Paper. Price 4.80 marks. Pp. 256, with twenty-five illustrations. Bonn: A. Marcus & E. Webers, 1914.

This little book is a reliable and up-to-date presentation of the subject of diseases of infancy. Inasmuch as pediatrics has largely to do with the infant it naturally follows that so concise a book contains little if anything that is not found in the larger standard text-books on diseases of children.

MENINGOCOCCUS MENINGITIS. By Henry Heiman, M.D., Professor of Pediatrics, New York Polyclinic School and Hospital, and Samuel Feldstein, M.D., Lecturer on Pediatrics, New York Polyclinic School and Hospital. With Introduction by Henry Koplik, M.D., Chief of Service, Mount Sinai Hospital, New York. Cloth. Price, \$2.50. Pp. 313, with 39 illustrations. Philadelphia: J. B. Lippincott Company, 1913.

This monograph is founded on the study of cases occurring in the clinic of Henry Koplik at the Mount Sinai Hospital. In his introduction Dr. Koplik calls attention to the fact that in spite of the value of the Flexner serum the results of the disease on those who recover, especially when the patient is less than 1 year of age, is still extremely serious. The physician needs in coping with this disease every aid to diagnosis and treatment available. The authors have added to their personal experience a review of the literature and have produced a satisfactory account of the disease. The laboratory technic described is such as the practitioner can expect to make use of in his daily work; the technic of spinal puncture and injection is given in a way that may be easily followed. The diagnostic aids to be derived from an examination of the spinal fluid are fully described. These are well summed up in a table adapted from Pfaunder and Schlossman giving in parallel columns the findings in various diseases. The book is well illustrated.

TUBERCULOSIS: ITS CAUSE, CURE AND PREVENTION. A Revised Edition of the "Great White Plague." (A Book for Laymen.) By Edward O. Otis, M.D., Professor of Pulmonary Diseases, Tufts College Medical School. Cloth. Price, \$1.25 net. Pp. 326, with illustrations. New York: Thomas Y. Crowell Company, 1914.

The author does not find that in the five years that have elapsed since his book was first issued under the title "The Great White Plague" any startling discovery has been made regarding either the nature or the cure of tuberculosis. Nor have the methods of fighting the disease been materially changed. The fight is more intense and is carried on with greater resources. The disease is steadily decreasing, and past success brings courage and hope. In the revision the form and substance of the book have been retained with only such changes as increasing knowledge have rendered necessary to bring it up to date.

Why Progress is Slow.—In one of his aphorisms Wundt says that "men think very little and very seldom." The truth of this dictum is indisputable. . . . Herbert Spencer walked about London, notebook in hand, listening to and writing down the matter of the conversation of passers-by. He found it to be of the most ordinary character, chiefly personal, such as "And how was Jemmy when you left him?" or, "She never gives more than tenpence a yard for it," etc. And action, like thought, is often of the simplest kind; however difficult at first to acquire, it has become an easy and self-sustaining reflex. When active thought or energy of a new kind is carried on for a long time or under stress people break down under it; the work can be done for only short periods. It is the custom to point to the great age to which scientific and other very busy men live; but when they do it is because they have as a rule an occupation which they are fitted to carry on without strain.—T. Clay Shaw, *Lancet*, London.

Miscellany

Ready-Made Ligature

The surgical knot illustrated is made on the forceps, the tip of the forceps being slipped through the superposed loops C and D. The loose knot is then slipped back on the forceps nearly to the handle and the vessel is clamped with the forceps as usual. Then the knot is slipped over the tip of the forceps and on the vessel and the ends drawn tight. No further tying is required. The knot was devised by M. G. Wunderlich of Guatemala, and the various steps of its application are illustrated in the *Cronica Medica* of Lima, Peru, 1914, xxxi, 205.

Surgical Knot

Ethical Advertising—Hints to Certain Medical Journals

Press dispatches indicate that at the Toronto meeting of the Associated Advertising Clubs of America, the keynote of most of the meetings of the different sections was devoted to the consideration of a higher standard of ethics among newspaper publishers and advertising men. It was stated that one meeting discussed the formation of a publishers' organization with a "clean page" as a standard. Most of the speakers took the position that the publishers could no longer deny their responsibility in safeguarding their readers from false advertisements.

While the medical journals should be the first to clean their pages, in this respect it is, nevertheless, a fact that some of the sheets going to doctors' offices throughout the United States carry advertising of the most untruthful and dishonest type. Responsibility of the medical journals' editors cannot be denied. More than that, their responsibility is much greater than that of an ordinary newspaper man, who may be excused from knowing a great deal about the ethics of the medical matter appearing in his pages.

The writer has rarely ever had the heart to criticize the daily newspapers for carrying "Pennyroyal Pills," "Ladies' Safe and Sure," "Peruna," etc., when his desk is covered up with medical journals advertising a delectable line of fakes. We should not forget that physicians may be influenced to use some of the worthless stuff they read about. Oregon has gone so far through the Oregon Social Hygiene Society to influence the legislature to pass an act prohibiting the publication of any advertisements "intended to imply that the advertiser will restore manly vigor, treat or cure lost manhood, stricture, gonorrhea, chronic discharges, gleet, varicocele or syphilis." We all know this is a sensible thing to do. . . . We should not wait for the people to regulate our affairs. The next step of the Oregon legislature would be to prohibit the advertising of fake remedies in medical journals. This would be, and properly, a stinging rebuke to the medical editor and it should not be necessary. Most of them know when their stuff is not acceptable, but the power to regulate it immediately lies with the individual physician. If he should ask the publisher to discontinue his dishonest advertisements that would settle the matter.—*Jour. Oklahoma State Med. Assn.*

The Influence of Schoolbooks on the Eyesight

The study of this question has been made by a committee of the British Association for the Advancement of Science. The report is published in the Proceedings of the eighty-third meeting of the British Association for the Advancement of Science (London, 1914, p. 268). The committee reports that, while attention is given in British schools to the detection and correction of visual defects in school-children, the influence of schoolbooks on the vision is practically ignored. The committee believes that the influence of books on the immature eye of the child is an important

one, and that, hygienically, the later children begin to read from books the better. The suggestion is made that little, if anything would be lost educationally by postponing the use of books in school at least until pupils have reached the age of 7. Oral instruction, wall-charts, blackboards, large pictures and other objects easily seen at a distance are recommended as substitutes for books in school.

The committee suggests a standard of book production, the adoption of which by educational authorities would render unprofitable the publication of books of a lower standard.

Among the hygienic requirements to which schoolbooks should conform the following are enumerated:

The surface of the paper should be neither glossy nor soft. The print of one side should not show through from the other, and the impression of the type on one side should not affect the evenness of the surface of the opposite side.

Books should be stitched with thread, so as to open flat. In books clipped from side to side with wire staples, the convex surface of the page gives rise to eye-strain.

For young children, illustrations from pen and ink drawings are preferable to halftones from photographs and wash drawings. The lettering of diagrams should be large enough to be read easily. Glazed paper may be used for halftone illustrations; it should never be employed for the text.

The ink should be a good black, and evenly distributed. The use of colored inks for reading-matter is strongly deprecated.

Worn stereotypes should be discarded. The ordinary text of schoolbooks intended for continuous reading should not be printed in double columns.

In regard to type faces, the committee expresses no preference between "modern" and "old style," but insists on a clean cut, well-defined type, neither too heavy nor too thin, not elongated vertically, and without excessive contrast between the finer and the heavier strokes. The general form of the letters should be broad and square, with a lateral shoulder on each type so that the letters are distinct. Long serifs should be avoided.

The size of type faces is considered the most important factor in the influence of books on vision. It is of the first importance to induce the young reader to keep a sufficient distance between eyes and book. Specimens of type faces considered acceptable for use at various ages are shown in the report. For children under 7, the smallest type presented has a minimum height of face for the short letters of 3.5 mm. (a little over $\frac{1}{8}$ inch). The use of type as small as that of the editorial pages of THE JOURNAL is not considered advisable for children under 12.

Very long lines of type necessitate great excursions of the eye and make it difficult to pass from one line to the next. Very short lines demand too frequent a change of direction in the movement of the eyes. A line of 4 inches for the largest type and $3\frac{2}{3}$ inches for the other sizes is recommended. Children 8 years old should not have their reading confined to very short paragraphs.

Good margins are restful to the eye and well worth their slight cost. The width of the outer edge in any schoolbook page should not be less than half an inch, and the width of the inner edge not less than three-eighths of an inch.

Copies of exercises, examples and questions produced by the hektograph or other multiplying process should be clear and legible.

It is better to multiply maps than to put much detail into one.

The Labeling Vice

Human vanity eyes all versatility with hostile suspicion. Most of us cannot do even one thing well, and we seldom have sportsmanship enough to applaud the man who excels at two or three. We prefer to label him with the first one of his achievements that attracts our notice. As for any thing else he may do, we look it over and then firmly declare "None genuine without the original label."—R. H. Schauffer, *Century*.

Death from Non-Abortive Anesthetic

(*State vs. Tippie (Ohio)*, 105 N. E. R. 75)

The Supreme Court of Ohio holds that whoever, with the intent to procure the miscarriage of a woman by the use of an instrument or other means, administers to her a non-abortive drug as an anesthetic preparatory to the use of such instrument or other means of procuring an abortion, and the woman dies in consequence of the administering of such drug before the use of instruments or other means by such person to produce such miscarriage, and it does not appear that such contemplated miscarriage is necessary to preserve her life, or that the procuring of such miscarriage was advised by two physicians to be necessary for that purpose, is guilty of a violation of the provisions of Section 12412 of the Ohio General Code. Under such circumstances every act done and performed in furtherance of such unlawful purpose is an integral part of the whole unlawful transaction, and the fact that death ensues before the final act in the contemplated crime can be accomplished is not a defense to an indictment charging a violation of this section.

If it appears, however, that a non-abortive drug is administered to a woman as an anesthetic to enable a duly authorized and practicing physician fully and carefully to examine into the woman's actual condition for the purpose of determining if it be necessary to produce a miscarriage in order to save her life, and the woman dies from the effect of the drug so administered, and no miscarriage is produced, nor intended to be produced unless the examination discloses that it is necessary to preserve the woman's life, no offense has been committed within the provisions of Section 12412.

Evidence tending to show that no secrecy is maintained in the transaction, that a second physician is called in to administer the anesthetic, that while the woman is in a state of anesthesia the attending physician makes an examination for the purpose of determining whether the fetus is alive or dead, and on such examination does determine that the fetus is still alive, and that it is not necessary to procure a miscarriage in order to preserve the woman's life, and, having so determined, makes no use of any instrument or other means to procure a miscarriage, but immediately desists from further efforts in that direction, and directs that the woman be restored to consciousness, is proper evidence to be admitted for the purpose of showing the absence of criminal intent in administering the anesthetic.

Accident Deemed Cause of Death Notwithstanding Organic Weakness

(*Moon vs. Order of United Commercial Travelers of America (Neb.)*, 146 N. W. R. 1037)

The Supreme Court of Nebraska holds that it could be said that the death of the insured in this case was caused by external, bodily injury when, while going up the steps leading into his yard, he accidentally slipped and fell with force and violence, striking his external body near the region of the heart on a large stone with such force as to cause a rupture of the left auricle of his heart, from which he immediately died. The jury were warranted in finding that the accident was the proximate cause of the death, although the condition of the heart and other organs of the body of the assured may have the more readily permitted the rupture, it not having been shown that death would have ensued at the time it did but for the accident. The fact that a person of 50 or 55 years of age would be likely to have a normal hardening of the arteries in parts of the body, which might tend to bring about a rupture of the heart in case of a violent accident of the kind occurred in the instant case, is not sufficient to show that the accident was not the proximate cause of the death of the assured. If insurance is to be defeated because of the fact that the walls of the heart grow thinner by advancing years, or the arteries become sclerosed, or the valves of the heart act improperly, and this condition

is the result of age, then the collection of the insurance money may nearly always be defeated by the effect of increasing years, which change the condition of the assured. The court does not believe this to be the policy of the law.

Proof of Illegal Practice of Medicine

(Hathaway vs. State (Ga.), 81 S. E. R. 260)

The Court of Appeals of Georgia holds that, in a prosecution for practicing medicine illegally, the state is required to prove that the accused, with intent to receive compensation therefor, performed services such as are defined in Section 1683 of the Civil Code of 1910, without registering in the county of his residence as required by Section 1684. The burden is on the state to prove, as a material fact in the case, the residence of the accused as alleged in the indictment; but the prosecution may rely on the failure of the accused to attack prima facie or presumptive proof as to residence which is sufficiently strong to compel the production of affirmative proof in order to rebut it. The court says that, according to the record, the volume of practice done by the accused in this case was exceedingly small. He made a poultice from herbs, which he gathered in the suburbs of Atlanta, and applied it to the arm of the keeper of the hostelry where he was boarding, and he supplied one of the chambermaids with a bottle of "Klondike Kidney Cure," which appeared to have relieved her of a severe case of stomach-ache. The real point in this case was whether the services rendered by the accused were humanitarian on his part, and purely charitable, or whether they were performed with the intent to receive compensation. The evidence in favor of the prosecution on this point was weak and unsatisfactory, but it was sufficient to authorize a verdict of guilty, if the jury believed the witnesses for the state. The court does not think the jury would have been authorized to convict the accused on the complaint of the maid who had "awful" pains in her stomach, and who had her employer to pay the accused 50 cents for the medicine, which "did her good right away," for that showed nothing more than a sale of a patent nostrum. The testimony of the prosecuting witness, however, who, after detailing the services rendered and that he was benefited by the treatment, testified that: "He made some poultices and bandaged them on my arm, and gave me some pills, . . . and for his services we agreed that I should give him credit for \$2.50 on his board at my house, which I did. He took the \$2.50 on his board," came clearly under the terms of Section 1683 of the Civil Code, and there was positive uncontradicted testimony that the accused had not complied with the requirements of Section 1684. The evidence authorized the verdict of guilty.

- 11 Digestive Disturbances of Artificially Fed Babies. I. M. Snow, Buffalo.

2. Casein in Infant-Feeding.—A method is given by the authors for preparing dry powdered paracasein for use in infant-feeding. It is shown that this paracasein is very easily digested and absorbed, and judging from the elimination of creatinin and creatin, it seems possible to maintain normal nitrogen metabolism by its use in infant-feeding. It is shown further that disturbances (fever, toxic symptoms, etc.) do not result from feeding this paracasein in exceptionally large quantities for seven days, even if fed with only the small amount of whey carried in 68 c.c. of 32 per cent. cream.

5. Diagnosis of Whooping-Cough by Complement-Deviation Test.—The authors' results lead them to the opinion that the complement-deviation test is of the greatest possible value in the diagnosis at all stages. Eighteen cases tested during the paroxysmal stage gave positive reactions: 3 + in each case. Nine of the cases were in the first week of the cough and 3 early in the second week. In no case did a normal give a positive reaction. This series included several cases of bronchitis. Of the 12 early cases, tested in the catarrhal stage, 11 gave positive reactions, and in each instance the definite whoop appeared later, thus confirming the serologic diagnosis clinically. The one case that gave a negative reaction was tested at the very beginning of the cough. The sister had given a positive test. Two weeks later the child with the negative test began to whoop. The one case giving a positive test that never whooped, occurred in a child with paroxysmal cough and vomiting lasting over a period of four weeks, evidently an atypical pertussis. The technic of the test employed is described in detail.

7. Circumcision in Masturbation of Female Infants.—Freeman is convinced that the masturbation of female infants occurs in nervous children, the stimulating cause being adhesions about the clitoris such as exist in practically all female infants. The treatment of this condition by braces alone is palliative and not curative. The only curative treatment is by separation of the adhesions and circumcision, and the result of such operative interference is often satisfactory.

Accident Deemed Cause of Death Notwithstanding Organic Weakness

(*Moon vs. Order of United Commercial Travelers of America (Neb.)*,
146 N. W. R. 1037)

The Supreme Court of Nebraska holds that it could be said that the death of the insured in this case was caused by external, bodily injury when, while going up the steps leading into his yard, he accidentally slipped and fell with force and violence, striking his external body near the region of the heart on a large stone with such force as to cause a rupture of the left auricle of his heart, from which he immediately died. The jury were warranted in finding that the accident was the proximate cause of the death, although the condition of the heart and other organs of the body of the assured may have the more readily permitted the rupture, it not having been shown that death would have ensued at the time it did but for the accident. The fact that a person of 50 or 55 years of age would be likely to have a normal hardening of the arteries in parts of the body, which might tend to bring about a rupture of the heart in case of a violent accident of the kind occurred in the instant case, is not sufficient to show that the accident was not the proximate cause of the death of the assured. If insurance is to be defeated because of the fact that the walls of the heart grow thinner by advancing years, or the arteries become sclerosed, or the valves of the heart act improperly, and this condition

27. **Ovarian Extirpation and Vasomotor Irritability.**—Hoskins and Wheelon found that ovarian extirpation in dogs results within six to eight weeks in a marked augmentation in the vasomotor reaction to a standard dose of nicotin. The reaction to epinephrin is not similarly increased. These results in conformity with clinical evidence indicate that the operations cause a heightened irritability in the sympathetic nervous system.

29. **Ultramicroscopic Clotting of Blood.**—Howell gives a description of the phenomena observed under the ultramicroscope when solutions of thrombin are added to oxalated blood-plasma or to solutions of fibrinogen. The essential point is that the fibrin formed is deposited not as a network but as separate well-formed needles of crystalline appearance which are massed to produce a mesh. Under certain conditions the process is incomplete, giving rise to the production of threads or rods of different lengths in place of the needles.

32 Behavior of Amelie Dysentery in Lower Animals and Its Bearing on the Interpretation of the Clinical Symptoms of the Disease in Man. W. A. Baetjer and A. W. Sellards, Baltimore.

30. **Thymus in Exophthalmic Goiter.**—It has been Halsted's practice of late in his strumectomy operations to investigate the contents of the space between the trachea and the manubrium with the object of determining the possible presence of an enlarged thymus. Only twice has he found it enlarged. The thymus symptoms predominated (attacks of dyspnea, diarrhea, no tachycardia, not much enlargement of the thyroid and not very definite eye symptoms). That the thymus plays an important part in Graves' disease, has been demonstrated beyond question by the results which have followed thymectomy. From the post-mortem examination of cases of exophthalmic goiter which have died of intercurrent disease it has been ascertained that the thymus gland is persistent in about 82 per cent. of them; and in those cases which have died of heart failure after operation enlargement has been found in about 95 per cent. At the Johns Hopkins Hospital there has been only one opportunity to make a necropsy on a patient with Graves' disease who died after operation. In this instance a long thick thymus gland was found tapering out from near the top of the manubrium sterni to the auricles of the heart.

From the facts gleaned at the autopsy table, from experiments on animals, and above all, from the results following primary thymectomies. Halsted has convincing evidence that the thymus gland may play an important part in exophthalmic goiter, and in some cases assume the title rôle. Some of the most puzzling features of the disease are made possible of interpretation by the discovery of the influence which the thymus may exert. Primary thymectomies uncomplicated by strumectomy and secondary thymectomies in cases not sufficiently relieved by resection of both lobes of the thyroid, Halsted says, would be the operations of choice for those searching for the essence of the Basedow symptoms. The combined operation would be avoided by them as much as possible until it became more definitely known how profoundly and in what particulars the thymus may influence disease.

53 *Cardiac Hypertrophy. T. F. Cotton, Montreal.

53. **Cardiac Hypertrophy.**—One hundred and fifty hypertrophied hearts were examined by Cotton. Of the kidney cases the greater number were of the interstitial type with hypertension and cardiac enlargement. In all the increase in weight of the whole heart was constant; the values of the relative weights of the ventricles, however, varied within wide limits. In some there was a marked hypertrophy of the left ventricle, in a few right hypertrophy predominated, while in many the normal relationship of the two ventricles was maintained. Microscopic sections showed myocardial degeneration in many; this was difficult to establish in a few. Cotton suggests that the altered state of the heart muscle may play an important rôle in the development of hypertrophy in the different chambers of the heart, while in many cases of hypertrophy associated with aortic valve lesions the hypertrophy was borne by the left ventricle. Cotton not uncommonly found a general hypertrophy, and in some a right hypertrophy, and this distribution seemed to bear no relation to the severity of the valvular lesion. He believes that here, undoubtedly, the back flow of blood during diastole into the left ventricle must increase the work of that chamber, and will explain in part the resulting hypertrophy.

Cotton would not look on the valvular defect as the essential factor in the production of the hypertrophy. If so, he says one should expect to find in those hearts with a general or right-sided hypertrophy, a greater incompetency of the aortic valves. In his case he did not observe any difference in the valvular lesions corresponding with the hypertrophy present. He did, however, note that a greater or less degree of muscular degeneration was generally present. Therefore, he would, as in renal cases, look on the degenerated myocardium as playing an important rôle in the development of the hypertrophy. In those hearts with mitral insufficiency, hypertrophy of the left ventricle was not a constant finding. In the majority of hearts hypertrophy was more developed in the left chamber, but in many the hypertrophy was general, the relative weights of the two ventricles being within normal limits, while in a few hypertrophy of the right ventricle predominated.

Only in one group of cases did Cotton's results corroborate the back pressure theory as an explanation of the hypertrophy associated with valvular lesions. In those hearts with mitral stenosis uncomplicated by any other valvular lesion, he found in every instance hypertrophy of the right ventricle predominating. Of those hearts with degeneration of the myocardium but with the valves quite intact, where the leaking or narrowed valve could not be a factor in embarrassing the heart's action, the results in the main corresponded with renal hearts. The hypertrophy was oftener of the left ventricle, not uncommonly the whole heart was increased in size, and occasionally the ratio of the ventricular weights was below 1.77, which he found to be normal.

56. **Psychic Factors of Surgical Anesthesia.**—Ferguson considers in detail the psychic phenomena of patients awaiting anesthesia and which the successful anesthetist must have clearly before him. Except under certain special circumstances, he does not believe in controlling the mind of the patient by drugs. He says it is always best to guide or subdue psychic phenomena by psychical technic. The endeavor of the anesthetist should be to have his patient believe that he knows his business and that he has perfect confidence in his patient taking the ether well. The method should be by action not words. Keep from the senses of the patient to be anesthetized anything and everything that could disturb him or impress on him undesirable ideas. Everything, even to the most trivial circumstances should make for tranquility of mind, and the leaving of pleasing impressions on the sensorium of the patient. If perfect trust in the anesthetist is wanting the patient will try to control the induction, thereby disturbing it, particularly when coordination of the senses is wanting. This negative condition, a lack of confidence, becomes positive distrust if anything that may be interpreted as deception occurs and early in the induction the patient antagonizes the anesthetist. Ferguson discusses all phases of this subject in detail.

As to the preliminary use of morphin, Ferguson objects to it because patients differ so in their idiosyncrasy to morphin that a correct dose is difficult to determine. It does away with the anesthetist's two most important waymarks, the character of the respiration and the light reflexes of the pupils. Unless administered in undue quantity, morphin prolongs the induction and necessitates more ether to be used, since it diminishes both the number of respirations per minute and the amount of tidal air at each respiration. Morphin prevents the patient clearing the larynx if necessary. Morphin favors sudden respiratory arrest with a slow, intermittent respiration after it has been restored. Morphin favors postoperative nausea and vomiting. Morphin may allow asphyxia during recovery. The three classes of case in which Ferguson demands its use are these: 1. Nervous cases with marked physical manifestations. 2. Pronounced alcoholics. 3. Young or middle-aged men of a marked athletic type or build.

64. **Specific Treatment of Hay-Fever by Active Immunization.**—In the last four years Koessler had treated 41 hay-fever patients by active immunization with pollen extracts, made by his method. Five of these had the early spring variety of the disease, and all these began treatment after the disease was already developed. The remaining 36 had the disease was already developed. The remaining 36 had autumnal catarrh. Seventeen of these patients had prophylactic treatment, whereas, 19 were treated while symptoms of hay-fever were present. Four of these patients had been completely free from hay-fever, though remaining in their usual place of abode. Of these 4 patients, 3 had treatment during two years, and one during three years—for two to three months. The supreme test in patients who are apparently free from the disease, is a railway or an automobile

journey through flowering fields. Only these 4 patients of the 41 could stand this experiment; 2 of them have so far remained free for two years, and 2 for one year. Of the other 37 patients, 29 were markedly improved subjectively as well as objectively. The remaining 8 are considered objectively not improved, though 5 of them feel subjectively benefited. The marked improvement consists in later, milder and shorter attacks, in the possibility of remaining in town and at work for the first time in years, in a diminution or disappearance of troublesome cough and constitutional symptoms. Twenty-three of the 41 patients had previous asthmatic attacks during the day and night in the critical season. Of these 16 experienced an undoubted amelioration of this most distressing feature of the disease. Six of these hay-fever asthmatics had no asthmatic symptoms, though 5 of them still retained other symptoms of hay-fever. Others had only 2 or 3 attacks during the whole season, were little disturbed in their sleep during the night, while emphasizing the improvement experienced.

70. **Experimental Atherosclerosis.**—Although he does not arrive at any definite conclusions as the result of his experiments, Adler states, that in all probability the theory which bases atherosclerosis on a purely mechanical etiology will not prove tenable. Whether mechanical factors come into play at all, and if so, to what extent, remains to be seen. It seems almost certain, at least in our present state of knowledge, that chemical influences, subject possibly to more or less nerve control are dominant factors in the etiology of atherosclerosis. Perhaps it may be discovered also that cholesterolin and its various modifications and combinations, while undoubtedly an element of importance in atherosclerosis of the rabbit and human beings, may not be the sole predominant etiologic factor. If it should turn out that so simple a procedure as adding a certain proportion of hydrochloric acid to the food of dogs is sufficient to produce lesions of the blood-vessels closely analogous, if not wholly identical with human atherosclerosis, a revision of our present theories will become necessary.

71. **Spleen, Blood-Destruction and Regeneration, Hemolytic Jaundice.**—Krumbhaar and Musser conclude that the slight differences between the arterial and venous blood of the spleen are within the limits of error inherent in the methods of blood examination and are not be explained by a peculiar action of the spleen. In some instances peculiarities shown by the splenic venous blood are common to the venous blood of the general circulation. Banti and Furno's observation concerning the presence of free hemoglobin in the blood of the splenic vein is not confirmed.

They also found that fresh extracts of spleen are devoid of definite hemolytic action. Occasional trivial and irregular results, not to be explained, are found, but these occur likewise in the control extracts of liver and mesenteric lymph-nodes. Twenty-four-hour extracts prepared at low temperature, show little or no increase in hemolytic activity. Boiled splenic tissue, extracted in the cold for twenty-four hours, is inert.

Intraperitoneal injection of saline extracts of fresh spleen constantly causes a sharp increase in red cell count and hemoglobin content. The rise is evanescent, lasting but one or two days, and may be followed by an equally evanescent drop below normal. Similarly prepared extracts from other organs fail to give this rise. No noteworthy change is found in the resistance of the red blood-cells to hypotonic salt solution, or in the number of skinned or reticulated erythrocytes, after the injections of the various organ extracts. A temporary increase of polymorphonuclear and transitional leukocytes usually follows the use of spleen extract, but may occur also, though less frequently, after the injection of liver and kidney. The constant increase of red cells in the peripheral circulation after injection of spleen, in view of the tendency to anemia following splenectomy, suggests that the spleen normally may exert a stimulating effect on the formation of red cells in the bone-marrow. The feeding of fresh raw spleen to splenectomized dogs has no clearly defined influence in preventing the anemia which usually occurs after splenectomy.

72. Influence of Spleen on Iron Metabolism.—Austin and Pearce's studies give evidence of increase in the iron elimination in three of five dogs during a period of two weeks following splenectomy, but not in two other dogs. The occasional increased output of iron may have some relation to the anemia which occurs in the early weeks after splenectomy and which varies in degree in different animals. No evidence was secured of an increase in the iron output at one, nine and twenty months after splenectomy. From their own studies and from examination of the literature of the subject the authors conclude that the spleen does not exercise a constant and important influence on the iron metabolism of the body.

74. Cultivation of Human Sarcomatous Tissue in Vitro.—Two experiments were made by Losee and Ebeling in which fragments from human sarcomatous tissue were cultivated. It was possible to keep cultures of such tissue in a condition of active life *in vitro* for several generations. One culture was stained which was growing actively in its twelfth passage (twenty-one days). One other culture was carried through for twenty-four passages, that is, fifty-two days. It was possible to divide this culture in its fifteenth passage, making two, and after forty-eight hours incubation one of these cultures was fixed. Sarcomatous tissue grew as well during a few days as normal connective tissue. Afterward the rate of growth became less rapid and the tissue could not be kept alive for more than fifty-two days, while normal human tissue could be kept for sixty-eight days.

75. Removal of Calcium from Blood.—It was found by the authors that one may devise a fluid containing practically all the inorganic diffusible constituents of the blood except calcium, and use it to dialyze normal blood in such a way as to remove from it a large part of its calcium. The dialyzed blood when perfused through an isolated extremity produces an extreme hyperexcitability of the nerves quite like that observed in tetany. Since perfusion with blood of the same composition, but containing calcium in the proportion found in the normal blood, causes no hyperexcitability of the nerves it is evident that the hyperexcitability is due to the lack of calcium. This effect can be attained in only a slight degree by replacing the blood of a whole animal with the dialyzed blood, since under the conditions of the experiment the tissues cannot be sufficiently depleted of their calcium. It seems probable that the parathyroid secretion is not removed by dialysis, but is returned to the body with the dialyzed blood.

To bring this result into relation with the condition in tetany following parathyroidectomy, animals in tetany were bled and the blood was replaced in one case with normal blood, in the other with dialyzed blood poor in calcium. The normal blood immediately relieves the tetany and lowers the excitability, while the dialyzed blood does not. The authors believe, therefore, that this is a further proof that in the tetany of parathyroidectomy also the twitching and hyperexcitability of the nerves is due to lack of calcium in the blood and tissues.

77. Intravenous Injection, Tumor Growth and Cyclic Changes in Ovaries.—If six to seven days after copulation incisions are made under ether anesthesia into the uterus, and on the day following this operation one or several injections of hirudin are given, Fleisher and Loeb noted that changes set in the ovaries which correspond to those found at the time of ovulation; namely, a degeneration of all the follicles with the exception of the small ones. These degenerative changes are followed by the same developmental changes as in the normal cycle. This represents a second method of altering experimentally the periodicity of the sexual cycle, the first consisting in the early extirpation of the corpora lutea.

Under the same conditions intravenous injections of hirudin destroy, in the large majority of cases, the greater part of experimental placentomata through hemorrhages, and they prevent the remaining placentomatous areas from active proliferation. These injections may also cause abortion in pregnant animals. Intravenous injections at various places in the circulation, probably as a result of interference with the a tendency to hemorrhage at various places in the body, and these hemorrhages are prone to occur, especially in rapidly growing tissues, in which the blood-vessels are less resistant, as in tumors and in placentomata, also in the neighborhood of necrotic areas. In the stomach the hemorrhages may be followed by digestion of the tissues through the gastric juice. It is probable that there is a connection between the action of hirudin on the blood (coagulability and viscosity) and the tendency to hemorrhage. Withdrawal of blood, intravenous injections of distilled water, colloidal copper, nucleoproteid, or casein have no marked effect on the cyclic changes in the ovaries or on placentomata.

78. Circulation of Kidneys Following Ligation of Ureter.—During the first week following ligation of one ureter there is found an impediment to circulation which is removed on opening the distended pelvis and reducing the intrapelvic pressure. This impediment, therefore, is probably due to the compression of the blood-vessels within the kidney brought by dilated tubules and unyielding capsule, and also possibly to disturbance of circulation produced by the distention of the pelvis. The venous and arterial branches passing over this may be either compressed or in various ways distorted. During this period the anemia produced by the impediment together with pressure and other factors gives rise to changes in kidney tissues which reveal themselves microscopically as a swelling and degeneration of one ureter there is an impediment to the circulation other than due to intrapelvic pressure. This impediment is probably due to cicatricial changes in the organ, which tend to maintain the tubules dilated and in a position of encroachment on the space normally allotted to blood-vessels, and which manifest themselves microscopically as a connective tissue cell infiltration into the interstitial tissues of the kidney, and an increase in vascular cells of the tufts diminishing the caliber of the tuft capillaries. The increased amount of work thrown on the control kidney produces no lesions other than a hypertrophy, which permits a greater and more rapid circulation through its vascular system.

118. Operative Treatment of Aneurism of Aorta.—The plan of operation adopted by Kümmell in one case cited was to lay bare the aorta as much as possible retroperitoneally and retroperitoneally, and after compressing it to remove the sac and close the opening in the artery by suture. Therefore several ribs (the fourth to sixth) were resected at the spinal column, care being taken to spare the pleura, and a large enough opening produced in the wall of the thorax so that the hand could easily be inserted. The pleura, which was somewhat thickened, was not injured, so that it was not necessary to use the positive-pressure apparatus that was held in readiness. The pleura was pushed forward and the thoracic aorta laid bare without difficulty as far as the sac of the aneurism, which was found to lie above the diaphragm.

A rubber tube was laid under the thoracic aorta in order, if necessary, to utilize it for a temporary closing of the artery. Kümmell did not have to use it, but produced the necessary compression with the fingers. The thoracic aorta was compressed between the thumb and index finger of an assistant at the diaphragm and the upper boundary of the pulsating tumor that was now covered only with a thin skin; the sac of the aneurism was laid bare with a long incision, the tear which was already present enlarged, and masses of clot removed. In order to be able to see the lower part of the normal aorta at the edge of the sac, Kümmell split the diaphragm and laid bare the upper part of the abdominal aorta retroperitoneally, so that there was a free view of the field of operation, including the thoracic and abdominal aorta and the sac of the aneurism. The sac of the aneurism was larger than the fist and the original tear in it was 10 cm. long. Kümmell passed his index finger into the normal lumen of the aorta above and below the aneurism from the inside of the sac and trimmed the latter so that a vessel corresponding to the normal lumen of the aorta was formed. The aneurism had caused a bulging chiefly of the posterior wall of the aorta, and had left the part of the artery lying immediately behind the spinal column comparatively unaffected. The 10-cm.-long slit in the new-formed aorta, that was now freely exposed, was closed with a continuous suture and the digital pressure somewhat relaxed. As a little blood still emerged from some places, a second continuous suture was applied over the other without any special difficulty. During the compression the blood-pressure had risen to double its normal height from the exclusion of the greater part of the circulation.

The digital compression of the aorta had lasted about twelve minutes. As it was gradually relaxed and finally withdrawn altogether, the suture was found to be sufficient. Not a drop of blood exuded from the line of suture. The pulsation in both femorals was strong and the pulse in the dorsalis pedis could be distinctly felt. The operation had taken about an hour, and after its completion the patient was in comparatively good condition, which is attributed to the fact that he was anesthetized by the intravenous administration of ether, and the heart was kept strong by the continuous influx of salt solution and ether. But he gradually grew weaker and weaker, and finally died of heart failure.

125. Contractured Psoas Parvus Tendons.—In the cases of moderate contracture, McDonald says, complete thigh extension may be possible but painful. Restriction is definite. In the suppurative cases of appendicitis the contractured tendon may readily be overlooked because of the importance of terminating the operation at the earliest moment, of indulging in the least possible intra-abdominal manipulation, and because bowel and omental adhesions supervene. The cardboard-like edge of the shortened tendon is capable of damming—to a most troublesome degree—the cecal current, the relief of constipation after tenotomy being quite noteworthy, even while the patient is lying in bed. At present the stripping up of the peritoneum from the outer edge of the abdominal wound, as though to expose the ureter, seems satisfactory and feasible for exposing the tendon for tenotomy, when the abdomen is opened through the oblique incision. Prompt relief to the symptoms may be expected

after complete tenotomy. In the postoperative cases the leaning attitude of the patient may well suggest adhesions. The persistence of thigh flexion under anesthesia is characteristic. McDonald's patients were inclined to be neurotic.

127. Repair of Accidental Injuries of Rectum.—A colon tube is introduced into the anus and passed up the rectum to a point 1 inch above the injury. Through the anterior rectal wall and the portion of tube above the injury a transfixion suture of number two chromic gut is passed which firmly anchors the tube to the upper portion of the anterior wall. The peritoneum on each side of the defect and parallel with the rectum is incised for a distance of about two and a half inches. By this maneuver the upper rectum becomes mobilized, after the manner of Kocher for mobilizing the duodenum. By gentle traction on the tube protruding through the anus the two lips of the rectal defect are brought together and approximated by three or four interrupted mattress sutures.

Two Allis clamps, one on each side, are placed about one-half to three-fourths inch below the suture line for the purpose of fixing the lower segment. Traction is made on the tube and as a result the upper segment of the anterior rectal wall is "telescoped" into the lower rectal segment. There is thus produced an artificial intussusception of the anterior rectal wall. The original defect or injury is carried down into the lower bowel and by the rolling in of the anterior rectal wall a peritoneal approximation is assured. A right-angle Cushing suture of Pagenstecher thread is passed along the site of peritoneal contact, completing the repair of the rectum. The lateral peritoneal defects are closed and the tube sutured to the anal margin with silkworm gut, thereby making gentle but firm traction on the upper rectal segment.

131. New Method of Circumcision.—In Thornton's method the prepuce is slit dorsally between two artery clamps. By passing a fine needle, threaded with silk, through the skin and around the superficial vessels they may be lightly ligated near the line of incision. The ventral margin of the prepuce is grasped by a clamp. At intervals of about three-sixteenths of an inch, number nine milliners' needles threaded with fine black silk are placed through mucosa and skin in a line around the penis about one-fourth inch from the corona of glans penis. The redundant prepuce is removed by cutting with scissors around the line marked by the needles. Each suture is then drawn through and tied. Since all incised tissues are included in the sutures, hemorrhage should be controlled when sutures are tied. However, if there should be a bleeding point, an additional suture is placed.

This method of circumcision is said to have the following advantages: The line of incision in skin and mucosa is accurately marked off and held in place by the needles, preventing unevenness and loss of bearings. Complete hemostasis. Prevention of retraction of subcutaneous tissues. Prevention of dead space and subsequent hematoma. Prevention of exposure of subcutaneous tissue to infection. Less traumatism. Less pain and priapism following operation.

133. Use of Pituitary Extract in Labor.—Madill and Allan report the results of 147 cases, studied at the Rotunda Hospital. They found pituitary extract undoubtedly increases the strength of the uterine contractions. These strengthened contractions maintained their physiologic character. The best results were obtained when given during the second stage. Its use reduced the number of forceps operations, with consequent lessening of morbidity in these cases. It is safe for the mother, and at least as safe as forceps for the child. It gives improved results for both mother and fetus in cases of placenta praevia, if used in combination with version. The puerperium is normal.

134. Axillary Sup.—Under this title Foster describes Lane's method of giving free fluid to the support of the circulatory system. He reports his observations on fifty cases of general surgery. The fluid used is normal saline solution which is placed in a reservoir to which is connected a "Y" rubber tube with glass connections. The single tube of

this "Y" is sufficiently long to permit it to be coiled within a porcelain enamel basin filled with hot water kept at 110 degrees. The saline solution is also poured into the reservoir at this same temperature. Such an arrangement allows of a drop of from five degrees to ten degrees before reaching the hypodermoclysis needles. The reservoir is placed at a proper elevation so that sufficient column pressure is exerted to easily force the saline into the subcutaneous tissues. The hypodermoclysis needles are always kept very sharp that they may pierce the skin with ease. They are three inches long, with the lumen large enough to permit a free stream of the fluid.

After the patient is fully under the anesthetic the chest is laid bare. A section of the skin area just inside of the external border of the pectoralis major muscle over its most prominent part and above the mammary gland is cleansed with antiseptic soap. The suds is then wiped away and the skin perfectly dried with sterile gauze. This skin area is then painted with full-strength tincture of iodine. While the fluid is running the needles are introduced piercing the pectoralis muscle in a direction outward and slightly tilted downward until the needle point is seen to push the loose skin of the axilla before it. The point is then moved about slightly to make sure it is properly situated and free. The amount of fluid supped during any operation depends on the time consumed in operating. No case has supped less than 40 ounces and some cases have taken as high as 140 ounces during an operation. The average operation on an average sized individual will require between 75 and 90 ounces. At the completion of the operation the needles are withdrawn and the skin apertures sealed with collodion and sterile cotton.

1. Auricular Flutter in Acute Rheumatic Carditis.—Auricular flutter is often latent and unsuspected. As practical points for further investigation Sutherland suggests that attention be paid to the following possible indications of the presence of this abnormal form of rhythm: (1) Attacks of cardiac asthma (great dyspnea) occurring suddenly and without accompanying variations in the cardiac condition. In one case cited by Sutherland, there were two such attacks preceding the acute illness, and they were at the time diagnosed as asthmatic in origin. (2) A triple or galloping or cantering rhythm heard on auscultation. In two cases cited there was a triple rhythm present, heard both at the apex and in the neck. In Dr. Morison's case of jugulo-embryocardia, which was the first example of auricular flutter recorded, each auricular contraction was audible in the right supraclavicular region, the auricular rate being 240, while the ventricular was 114. (3) Pericarditis without effusion and with great respiratory distress. The inflammatory changes in pericarditis are usually earlier and more marked about the

auricles than the ventricles, and a disturbed auricular rhythm may follow from the active effusion in and around the auricular walls. (4) Dyspnea, cyanosis and enlargement of the liver out of proportion to the physical signs of disease of the heart. (5) The presence of the pulsus alternans. Further investigations will be required to determine whether in cases of acute carditis a disordered rhythm of this nature is often present.

3. Associated Movement of the Jaw and Upper Lid.—Cockayne's case occurred in a baby girl first seen at 6 months of age. The movements were first noticed when she was about a month old. The right eyelid went up and down as the baby sucked at the breast. The baby was fat and healthy looking, but there was a slight ptosis of the right upper lid, such that the lid fell as low as the level of the upper edge of the pupil. As far as one can tell in so young a baby, voluntary movement of the levator was good, and also of the other ocular muscles. The pupils were equal and reacted to light; there was no facial asymmetry, and no difference in size of the tarsal plates. As the baby sucked the right lid was raised synchronously with the movements of the jaw so that a little sclerotic was shown each time above the right cornea. As the jaw was moved away from the side of the lesion, as in grinding the teeth, the lid was raised. An almost imperceptible lateral movement was sufficient. The left lid was not moved, and the right eye itself remained stationary. Slight sucking movements produced no movement of the lid. When the baby yawned or laughed the lid was retracted to an extreme degree and showed a large extent of sclerotic. The movements are diminishing in frequency and in extent. There is no history of a similar condition or of ptosis in the family.

21. Osteo-Arthritis of the Hip.—Llewellyn and Jones comment on the extreme slowness with which the condition of

osteo-arthritis of the hip is established and emphasize the extreme length of time that may elapse before bony outgrowths can be detected. From their consideration, therefore, of the clinical features, supplemented by the results of roentgenography, they are led to postulate two stages in the life history of osteo-arthritis: 1. A primary or preosteophytic phase, often of prolonged duration, whose clinical characteristics are those of villous hypertrophy. 2. A secondary or terminal stage in which bony and cartilaginous outgrowths make their appearance.

Their presumption as to the villous nature of the disorder is based on the occurrence of attacks of pain with pseudo-locking sensations which come and go in the same erratic fashion that we are familiar with in the case of the knee. In addition, too, there is in some instances accessory evidence in the shape of villous overgrowths in the knees, which, of course, in this articulation are more easy of detection by palpation. In support of their contention the authors remark that if in so-called osteo-arthritis of the knees roentgenography be resorted to after routine fashion the same absence of bony outgrowths will be ascertained with striking frequency save in the more advanced cases. They are led, therefore, to the conclusion that this condition of osteo-arthritis, whether of the hip or knee, is invariably preceded by a long period during which the only local signs and symptoms clinically appreciable are those of villous hypertrophy. In other words, the villous overgrowths being more obtrusive mask as it were the early beginnings of fibrillation in the diseased cartilage.

Diagnosis of osteo-arthritis of the hip in its terminal stages presents no difficulty, but unfortunately at this period in its life history treatment is of little avail. The authors therefore urge that in all cases of so-called sciatica investigation of the movements of the hip should invariably be undertaken, for during the early or preosteophytic phases of the disease there is good reason to believe that the march of the morbid process may be arrested if care be taken to remove any sources of strain on the affected articulation. They indicate the importance of a reduction of body-weight if obese, as undue corpulence is undoubtedly an aggravating factor. Coincidentally any static deformity in the lower limb, whether in the direction of flat-foot or possibly inequality in length of extremities, either congenital or acquired—viz., shortening from malunited fracture—should, as far as possible, be corrected so as to diminish any mechanical strain. For the diseased joint itself, when painful or irritable, absolute or relative fixation by some form of ensheathing apparatus is indicated pending the decline of acute symptoms. It should be discarded only during the night and reapplied in the morning after massage, passive movements, and hyperemia or hydrotherapy, with or without thermal douches or hot-air applications, have been practiced.

25. Rigor.—Occurring in the course of apparent health, if there is no psychical disturbance, Taylor says, rigors suggest the onset of acute illness, as pneumonia or influenza; occurring in the course of a local inflammation, they suggest suppuration; occurring in the course of an apparently general infection, they suggest, but are by no means conclusive of local foci of suppuration. Their occurrence in typhoid fever, and in some cases of malignant endocarditis, shows that the

suppuration need not be there. In cases of gall-stone and renal calculus they are incidental, and have no significance other than that they point to the presence of a source of irritation. They may coincide in time with the maximum of obstruction, which just precedes the final passage of the stone to the type of individual is highly probable. The relation of a rigor is purely symptomatic.

26. **Leukoplakia.**—Barker urges that every patch of this affection should be watched closely, especially if it does not improve under treatment. On the slightest sign of activity in it, free excision should not be deferred. The first sign of cancerous change in such a patch is usually seen in the more advanced degrees. It generally begins as a crack in the white covering or at its ragged border. This fissure exudes blood or serum, and causes pain on movement of the part. It may break under washes, but in any case must be under suspicion whether it does or not. There is usually a feeling of stiffness in the area affected. It has lost its softness and indurated; then the crack deepens and widens, and the pain and discomfort increase. On finding this induration around a crack in an old leukoplakia there should be no hesitation in resorting to free local excision. The state of the glands carcinoma starting in leukoplakia has little tendency to spread along the lymphatics; that it is one of those forms of cancer which remain for a considerable time purely a local disease. On the whole it appears to Barker that the very pessimistic views held in some quarters, as to the inevitable transition of leukoplakia into carcinoma, have perhaps been overdone. It is a condition to be watched carefully, and one which justly excites uneasiness; but it is another thing to take it for granted that it is always the precursor of cancer, and to attack it at once by wide-reaching excision of the part itself and of the glands likely to be involved.

31. **Ringworm of Scalp and Beard.**—There are two main methods for the treatment of ringworm: 1. Old method, by means of the local application of a parasiticide. 2. New method, by Roentgen rays. Old method.—The hair should be cut as short as possible for at least 2 inches around the infected area. A better plan is to shave the head all over. The head should be washed daily with green soft soap, or an antiseptic shampoo wash, such as,

R Thymolis		gm. or c.c.	
Saponis mollis		1	or gr. xv
Sp. Vini. Rect.		30	3 i

This is allowed to remain some ten to fifteen minutes on the scalp before rinsing off. The hair around the edges of a patch, for at least 1 inch should be pulled out; this prevents spreading by continuity. A good ointment to apply before and during the period of epilation, is

R Cupri Oleatis		gm. or c.c.	
Hydrarg. Oleatis		4	3 i
Lanolini		1/66	gr. xxv
Ol. Olivae		30	3 i

The following prescriptions Freshwater has proved to be efficacious, and, he says, if persevered with, will ultimately lead to a cure:

R Acid Salicylic		gm. or c.c.	
Sulphur. Praecip.		2	or gr. x
Adipis		30	gr. xxx
Fiat ung.			3 i
R Sulphur		gm. or c.c.	
Acid. Salicylic		4	3 i
Naphthol.		66	gr. x
Hydrarg. Ammon.		30	3 i
Lanolini			3 i
Paraffin Liq.			3 ss
Fiat ung.			3 iii
R Sulphur		gm. or c.c.	
Acid. Carboli		2	or 3 i
Lanolini		20	3 ss
Paraffin Liq.		12	3 iii
Fiat ung.			

The following lotions are also serviceable:

R Formalin, 40 per cent.		gm. or c.c.	
Aquam		8	3 ii
R Acid. Salicylic		30	3 i
Spt. Lavand.		2	or gr. xxx
R Acid. Sulphurous		30	3 ii (fresh)
Aquae		8	5 vi
R Acid. Picric.		24	gr. viii
Camphor.		120	3 iv
Sp. Vini. Rect.		180	3 vi

The lotion should be applied with a brush twice daily for a month, when in favorable cases the stumps will have fallen. In small chronic patches and in the small widely spread patches of a disseminated ringworm, the application of croton oil is a valuable form of treatment. It is best combined with phenol (carbolic acid) or creosote.

Phenolis (Acidi Carbol)		1	Creosoti		3 ii
Ol. Croton		9	Ol. Croton		3 vi
R Acid. Salicylici		gm. or c.c.			
Ol. Lavandulae		66			gr. x
Ol. Bergamoti		30			m v
Ol. Olivae		30			3 i

Since the introduction of the treatment by means of epilation by Roentgen rays, the cure, even in obstinate cases, has been shortened to a few weeks.

33. **Intubation in Laryngeal Diphtheria.**—Thomson considers that intubation is the better operation because, in the great majority of cases, it is much more easily performed than tracheotomy, no preliminary preparation is needed; no anesthetic is required, skilled assistance is not essential; as there is no cutting, and no subsequent scar, the consent of the parents is readily obtained, the operation can be very rapidly performed, even with the patient in bed, and without good sufficiency of air to enter. If dyspnea is not relieved, no harm is done. Tracheotomy can then be performed. The after-care, so important in tracheotomy, is a simple matter.

39. **Test Diuresis with High Blood-Pressure.**—Cottet expatiates on the clinical importance of induced polyuria, viz., the diuresis which follows drinking a pint (600 c.c.) of a mild mineral water in the morning, fasting, and on the clinical importance of the proportion between the amount of urine voided during the night and the day. The normal portion is about $\frac{1}{2}$. He regards this "rhythm" of the proportional output day and night as of great diagnostic value. Other conditions being equal, this rhythm persists unmodified in the individual case; the amount of urine may vary widely at different times, but the proportion keeps up unchanged. Good effects from a course of mineral waters are possible only when the induced diuresis test shows that the way through the kidneys is open. With a high blood-pressure, neglect to ascertain this may lead to great harm from a course of mineral waters. Persons with arteriosclerosis and kidney disease often drink unusually large amounts of fluids, hoping thus to "wash out the system." If the kidneys are

below par this excess of fluids is not eliminated properly and it gorges the vessels and may do direct mechanical injury. Cottet cites Janeway's statement that 79 of 100 patients with high blood-pressure died with symptoms suggesting chronic kidney disease. Impending uremia is a superposed danger with high blood-pressure, and unless it can be warded off the prognosis is grave indeed. Tests for induced polyuria throw light on the conditions. The special features of the technic and findings of the test were given in *THE JOURNAL*, 1913, ix, 90.

44. **Lesions of the Thyroid Gland in Exophthalmic Goiter.**—Roussy and Clunet give an illustrated description of the changes they found constantly in the thyroid gland in twelve cases of exophthalmic goiter and never in ordinary goiter or in mere thyroiditis. These lesions are so characteristic, they say, that microscopic examination of a single scrap will serve to differentiate the disease without further data. The changes found suggest that drugs to combat infection, sodium salicylate, quinin, arsenic, mercury, may be useful at first. When the lesions are once established, palliative organotherapy or removal of the thyroid or thymus is indicated unless radiotherapy is given the preference. This acts more like a gradual natural process, and has the advantage that it acts on both thymus and thyroid.

49. **False Pulsus Alternans.**—Gallavardin and Gravier expatiate on the remarkable light thrown on pulsus alternans by electrocardiography. It has shown that pulsus alternans is produced sometimes by the respiratory movements alone or by extrasystoles. This of course does not have the clinical significance of true pulsus alternans. He gives tracings from a case of false pulsus alternans from what he calls auricular bigeminism and another due to "extrasystolic trigeminism"—both exceptional cases. The tracings from another patient show two or three weak systoles occasionally in the midst of an apparently regular pulsus alternans. This spontaneously upsets the regular alternation. He encountered this in only one case out of fifty examined with electrocardiography and it did not recur during the later examinations in this case. When it happens that the respiration-rate is exactly one-half of the heart-beat, the tracing shows that each second peak is lower than the first; this regular depression of every second peak runs through the tracing unless the breath is held during a few heart-beats. When the respiration is thus shut off, the peaks run regularly at the same height.

51. **The Blood in Scorbutus in Adults.**—Heitz tabulates the blood-findings in a woman who developed scorbutus after prolonged errors in diet. They confirm the findings of the Japanese in thirty-five Russians taken at the fall of Port Arthur, De Albertini's in ten Italians and those of Austregislo at Rio de Janeiro in thirteen insane persons with scorbutus. The blood-picture does not seem to be much modified by the scorbutus; there is merely a tendency to

anemia, with whites somewhat below normal and slight polynucleosis.

54. **Radium as Adjuvant to Operations for Cancer.**—Jayle reports two cases of extensive malignant disease of both ovaries or the uterine cervix in women of 32 and 33 in which he applied radium treatment at once after radical operation and there has been no sign of further trouble during the five and a half and three years since. These were among the first gynecologic cases in which radium was applied. He cites further two cases from Desjardins' service in which over five and three years have elapsed without signs of further trouble although the operative removal of the organs involved was far from complete. In a recent case an absolutely inoperable cervix cancer was modified by seventy hours' exposure to 11 cg. radium sulphate so that it could be safely removed.

55. **Acute Osteomyelitis of the Jaw in the New-Born.**—Broca describes a couple of typical cases of acute osteomyelitis in the upper jaw in quite young infants. He has encountered ten such cases in the hospital and one private case and five died. The swelling and inflammation start in the upper jaw but spread so rapidly to involve the orbit that the trouble is often mistaken for ophthalmia. The bloody-purulent nasal discharge and the signs of severe intrabuccal inflammation and fistulas soon clear up the diagnosis. This is facilitated by the non-involvement of the upper lid in the process and by the serous character of the conjunctival secretion and absence of gonococci. Erysipelas may be suspected at first but the intrabuccal swelling and fistulas and the involvement of the three surfaces of the upper jaw soon render erysipelas less probable. The osteomyelitis in these cases affects the germinal tissue of the two temporary molars. He thinks it is of blood-borne origin, from some general infection, possibly traceable to the umbilicus. The osteomyelitis was installed by the third day after birth in one of his cases, and in Fürst's case a bloody purulent nasal discharge was noted by the eighth day. Nine of his eleven little patients were boy babies.

The septic reaction varies within a wide range and the outcome depends in large measure on the promptness with which the abscess is incised and the posterior portion of the jaw scraped out, bringing away the germinal tissue involved. If there is a suborbital fistula he cures and drains between the skin and the vestibule of the mouth. The child must not nurse for a few days; it is better to draw the breast milk and feed it to the infant. He generally operates under a little chloroform if he deems any anesthetic necessary. In one case the trouble kept up until after a few months a sequester was curetted out. The osteomyelitis of the upper jaw is less tenacious than when the lower jaw is involved. Healing, once started, proceeds rapidly but the destruction of the germinal tissue of the teeth may affect dentition, and it is irreparable.

57. **Insufficiency of Expiration in Children.**—Göppert calls attention to a group of cases among children with a chronic or recurring cough in which the lower margin of the lungs is found continuously below the normal level, although neither the clinical manifestations nor the auscultation findings suggest this. By pressing on the ribs to aid in expiration the diaphragm rises to the normal level, showing that there is no mechanical obstacle to normal expiration. The children thus affected are generally of the pronounced exudative diathesis type, that is, with an inborn predisposition to chronic swelling of mucous membranes. Lichtwitz has noticed a similar tendency to insufficient expiration in young adults with constitutional eczema. The cause is probably some impediment in breathing which is overcome in inspiration but hinders expiration, probably some congestion and catarrhal secretions plus possibly a tendency to spasm of the bronchi. A tendency to catarrhal oversecretion plus congenital subnormal elasticity of the lung tissues are probably the main factors involved.

The deficient expiration is fraught with various dangers and must be combated. This can be done only by training the muscles to expel the breath effectually. Even children of 4 or 5 can exercise the muscles in this way, taking a short breath and expelling it slowly and emptying the lungs. Under these exercises extra quantities of sputum are expelled, and frequently a previously intractable cough may be cured by this means. This confirms the existence of catarrhal conditions and shows that such persons are particularly prone to emphysema, etc., and should be watched over with special care. He has the exercises repeated two or three times a day, three deep-expirations and then a pause of two or three minutes, repeating this three or four times. At first the expiration must be aided by compression of the chest from the rear by the hands of an adult, also impeding inspiration.

58. **Abnormal Fear of Blushing.**—Bernhardt gives the confessions of two men who suffered so intensely from a tendency to blush on the slightest excuse that one even spoke of suicide. Both were evidently the prey of neurasthenia and were psychopathic. Treatment in such cases, he says, must be mainly psychic, possibly with hypnosis, as adjuvant to drugs to steady the unstable nervous system and physical measures to tone it up in general.

59. **Sterilization by Ultraviolet Rays; Especially after Spraying with Stain.**—Friedberger's further research, he states, has confirmed his previous announcement that vaccine can be sterilized in thirty minutes, without impairing its potency, by exposure to the ultraviolet rays. He also reports tests of the influence of these rays on amoebae, complement and antigen separately. Bacteria in urine and blood seem to be protected against the ultraviolet rays unless sensitized by 1 to 100,000 or 1 to 1,000,000 eosin solution. This same favoring influence from eosin sensitization was observed also in experimental infection of the interior of the mouth treated by exposure to the ultraviolet rays or direct sunlight. The bacteria in the mouth were killed off so promptly and constantly that he thinks this method of radiotherapy after sensitization with a stain offers an encouraging prospect for treatment of throat affections in human beings and to sterilize bacillus-carriers. During the exposures he

sprayed the region repeatedly with the eosin or fuchsin 1 to 100,000 solution.

62. **Recovery after Removal of Brain Tumor.**—Alexander and Unger report a case of a large encapsulated tumor in the upper half of the posterior central convolution removed at one sitting under local anesthesia with complete recovery for the six months to date. At the age of 22 the previously healthy young man began to have epileptic seizures but the aura was usually long enough to permit him to stuff a handkerchief in his mouth to protect his tongue. He was under specialist medical care for four years and not until after this interval did symptoms develop pointing to a brain tumor. Even then the symptoms were mild in comparison to the size of the tumor; it was shown up well by the Roentgen rays. It extended into the lateral ventricle and the only defect left from its removal is a pure stereognosis, that is, loss of power to recognize objects by touch. Otherwise there seems to be complete recovery. The tumor must have grown very slowly and it already showed signs of calcification when exposed. The young man was conscious during the entire operation, even for a whole minute during which respiration was arrested, but he suffered no pain. A photograph shows the excised tumor implanted in a brain taken from a cadaver.

63. **Friedmann's Remedy for Tuberculosis.**—Friedmann devotes nearly nine pages to his description of his preliminary experimental work and the bases for his method of treating tuberculosis. He reaffirms that it should be used as a protecting vaccine for children in a tuberculous environment, and reiterates that its harmlessness for man is shown by the case-histories that have been reported.

64. **Early Diagnosis of Pulmonary Tuberculosis.**—Stern emphasizes the importance from this standpoint of a tendency to anemia, dyspepsia, diarrhea, tachycardia, especially paroxysmal tachycardia, and slight enlargement of the heart dulness toward the right; also pains in the shoulder or abdomen may suggest primary or secondary pleurisy of tuberculous origin. Another significant finding is a paresis of the vocal cord on the side of the lung lesion, associated with slight chronic laryngitis. He calls this the larynx sign of early pulmonary tuberculosis and advises direct visual inspection to detect it when there is a sensation of vague oppression in the chest, a tendency to rheumatic pains, slightly irregular breathing, or dyspepsia. The entrance to the throat is moderately red and the paralyzed vocal cord is also red. There is always more phlegm on the paretic cord than on the other, and its inner margin is usually irregular in outline. There is slight hoarseness, particularly at night, and the patient hawks often but raises very little sputum and tubercle bacilli cannot be found at this early stage. As the pulmonary process progresses or subsides, the throat findings become modified to correspond.

The pupil of the eye on the side affected is often more dilated than the other and the reaction to light is more sluggish. The musculature on this side is often less well developed, but this is not a consequence of but merely a predisposing factor to the tuberculous focus. The lagging behind of one-half of the chest in the excursion of the thorax is a sign of trouble within, usually involving the pleura. Nearly all the foregoing symptoms can be traced to pressure on nerves by enlarged bronchial lymph-glands. By heeding these signs we can recognize the tuberculosis even before the lung has become involved in the process to any extent.

the streptococcus-pneumococcus group has helped to a better understanding of the changing pathogenic specificity of these bacteria. Apparently transmutation of a strain of this group may occur in the focus of infection. The oxygen supply of the tissues about the focus seems to be an important factor in the transmutation of the micro-organism. In consequence it may take on characteristics which render it pathologically specific in the infection systematically of joint-tissues or of muscles including the myocardium, or of tendons and aponeuroses or of endocardium and pericardium or of gall-bladder or of mucosa of stomach and intestine or of pancreas, or of kidney, respectively. Apparently strains with an affinity for joint-tissues and muscles, or for joint-tissues, endocardium and pericardium may develop in the primary focus. Inoculations with strains obtained from patients suffering from chronic arthritis, rheumatic fever, with endocarditis and pericarditis, myositis, peptic ulcer (surgically excised), cholecystitis (surgically operated), chronic infectious endocarditis (blood-culture), have resulted in the production of the respective lesions in the experimental animal. The interesting experiments proving the transmutation of the streptococcus-pneumococcus group by Rosenow,⁴ and the positive results obtained by him in making cultures by new and ingenious methods, from tissues and exudates, in the various diseases named, have made clear many clinically obscure conditions. The transmutation of the strains in growth and specific pathologic characteristics explains, too, the varying and often contradictory results of various research workers in inoculation experimentation with animals.

METHOD OF SYSTEMIC INFECTION AND RESULTING MORBID ANATOMY

Probably the infective agent passes from the focus to other tissues through the blood-stream. Histologic examination of joint structures, heart-valves, muscles and other tissues of inoculated animals shows embolic bacterial masses in the terminal arteries. Endothelial proliferation at the site of the embolus closes the vessel lumen. Muscle and joint-capsule show embolism, local hemorrhage and endothelial proliferation closing the lumen of the vessels. The same process takes place locally in the submucosa of the stomach and intestine and of the fundus of the gall-bladder. Anemic necrosis and rupture into the gall-bladder is a cause of cholecystitis, acute or chronic, and if the latter, gall-stones may form. The specific streptococcus may invade vessels of the pancreas. Acute severe pancreatitis may result, or a lesser degree of infection may so diminish the blood-supply of the organ as to disturb its function, and temporary or severe glycosuria supervenes. Lessened nutrition and oxygen of the infected tissues due to the mode of infection bring about characteristic results. The anatomic changes in capsule, cartilage and bone of joints, in muscles, tendons and aponeuroses which are characteristic of chronic arthritis may be produced by ligation of some of the nutrient arteries of joints, muscles, etc. (Oxhausen⁵). Furthermore, the strains of streptococci which apparently cause chronic deforming arthritis and myositis grow best in a low oxygen tension and even grow anaerobically. The method by which they invade the tissues produces a condition of

the tissues in which they thrive. The peculiar characteristics of the mode of infection, the diminished blood-supply to the tissues, the resulting morbid anatomic change and the suitable mediums for continued viability and growth of the infectious agent, explain, in part at least, the progressive nature and the difficulty of successful management of arthritis deformans.

A characteristic directly opposite of this is evident in chronic infectious endocarditis due to the *Streptococcus viridans*. Here the infection is undoubtedly hematogenous. The scar of healed endocarditis and valvulitis is often predisposing. This infectious agent grows best in a high oxygen content. The circulating blood furnishes this in abundance. It causes an abundant vegetative growth on the valves and endocardium. In this nidus, swimming in oxygen it multiplies, becomes immunized against the host and resists every method of treatment.

Acute rheumatic fever is of undoubted focal origin. The newer methods of bacterial culture (Rosenow⁴) have proved the presence, usually, of the infectious organism in the joint-fluid, and it may always be found in the synovial membrane and proximal lymph-nodes during the height of the disease. The strain of the streptococcus which produces these acute lesions also has an affinity for the endocardium and pericardium and often for the myocardium and some groups of the skeletal muscles. Apparently the micro-organism has other affinities. One of the clinical group (Woodyatt) called attention to an apparent thyroiditis in some of the patients suffering with acute rheumatic fever. The thyroid gland was palpably enlarged and tender on palpation. There was moderate tachycardia, tremor of fingers, unusual nervousness, excessive sweats and diminished carbohydrate tolerance. Of five patients then in wards, suffering with acute rheumatism, three showed this evidence.

CASE 1.—A. X., man, aged 35, married, porter, Greek, admitted, April 1, 1914. Diagnosis: Rheumatism, acute; tonsillitis acute; thyroiditis. Complaint: March 30, 1914, illness began with soreness of throat, chilliness, pain in lumbar muscles and left heel and swelling and much pain in knees. Profuse sweats at night. Anorexia, thirst and constipation. Had rheumatic fever in 1900 and several minor attacks since then. Examination: Well-nourished; teeth good; tongue, slight whitish fur; tonsils very large, red and infected; thyroid, palpably enlarged and tender; heart and lungs normal; spleen palpable; knee-joints hypersensitive but not swollen; profuse sweating; fine tremor of fingers; temperature from 102 to 104 F.; pulse 90 to 100; blood-pressure 125 systolic; blood, reds 4,440,000, whites 13,500, hemoglobin 70 per cent.; urine scant, 1,028, acid, albumin trace, casts 0. April 2, 7 a. m., glucose, 50 gm., given before breakfast. Urine voided and examined each hour. Glucose present only in specimen voided at 9 a. m. Treatment: Compound pills of rhubarb, as necessary; sodium salicylate and bicarbonate 1 gm. every three hours; oil of wintergreen and bandages applied to joints. April 18, discharged, recovered. Tonsillectomy advised and refused. April 19, readmitted for slight recrudescence. No joint-swelling and no fever. April 22, discharged; tonsillectomy refused. May 30, readmitted for tonsillectomy. Cultures from depths of tissue of excised tonsils yielded almost pure cultures of a green-producing streptococcus.

CASE 2.—P. K., man, aged 25, single, laborer, Greek, admitted, April 12, 1914. Diagnosis: Rheumatism acute; endocarditis; thyroiditis; tonsillitis acute. Complaint: Acute inflammation of many joints; began nine weeks ago with sore throat, fever, sweats, etc. In Francis Willard Hospital two weeks. Apparent recovery. Recrudescence three weeks ago with sore throat, pleurodynia and polyarthritis. Denies venereal disease. Examination: Well-nourished; sweating and

5. Oxhausen, G.: Ueber Einfache aseptische Knochen und Korpelnkrose, Chondritis desiccans und Arthritis deformans, Verhandl. d. deutsch. Gesellsch. f. Chir., Berlin, 1912, xlii, Part 1, p. 40, Part 2, p. 446.

hypersensitive skin; tonsils large, red and infected; teeth negative; thyroid gland palpable, enlarged and lobes tender to touch; heart, left border, dullness 13 cm.; systolic murmur at mitral area; second pulmonic tone accentuated; rate 100 to 110; many points swollen, hypersensitive and painful to movement; fine tremor of hands; fever, remittent 99 to 101 F. Reds 5,260,000, whites 10,300, hemoglobin 70 per cent; blood-pressure 135 to 145 systolic; urine scant, 1,022, acid, albumin 0, sugar 0, casts 0. April 14, 50 gm. glucose given before breakfast at 7 a. m. At 8 a. m. urine=sugar 0. At 9 a. m. urine=sugar present. At 10 a. m. urine=sugar 0. Treatment: Cleansing mouth- and throat-washes; sodium salicylate and bicarbonate each 1.3 gm. every three hours; oil of wintergreen and compresses of cotton applied to joints. April 17, joints still swollen and painful. Fine tremor of fingers, systolic murmur at mitral area. April 29, convalescent. Tonsils reduced in size and no visible infection. Thyroid gland comparatively smaller and not sensitive to palpation. Systolic murmur at mitral area. May 5, discharged recovered. Tonsillectomy advised.

CASE 3.—P. X., man aged 27, single, laborer, Greek, admitted, May 10, 1914. Diagnosis: Rheumatism acute; tonsillitis acute; thyroiditis. Complaint: Six days ago acute sore throat, which was followed in two days by painful swollen fingers and wrists and later all joints of extremities involved except hips and shoulders. Much sweating, headache and nervousness. Anorexia and constipation. Fever for six days. Similar attack six years ago. Denies venereal disease. Examination: well-nourished and developed. Face flushed. Skin sweating and hypersensitive. Tongue tremulous and coated, grayish-white. Teeth, sound. Tonsils large, red and infected. Thyroid, palpably enlarged and tender. Heart and lungs normal. Polyarthritides acute of all joints of extremities excepting shoulders and hips. Temperature 100 to 102.4 F. Pulse 100 to 120. Urine, 1,028, acid, trace of albumin and a few hyaline casts. Blood: Reds 5,020,000, whites 17,800, hemoglobin 70 per cent. Blood-pressure 110 systolic. May 12, 7 a. m., given glucose, 50 gm. In three hours voided in urine glucose, 1.34 gm. Treatment: sodium salicylate and bicarbonate, each 1.3 gm. every two to four hours; oil of wintergreen and compresses of cotton applied to joints. May 28, discharged recovered. Tonsillectomy advised.

A review of the foreign literature of the last seven years shows the recognition of enlargement of the thyroid gland in acute articular rheumatism as a frequent occurrence. Vincent⁶ was apparently the first to note the fact. During 1906 and 1907 he made several reports to the Société médicale des hopitaux de Paris. Nov. 21, 1907, he reported that of 186 patients suffering from acute articular rheumatism he observed swelling and tenderness of the thyroid gland in 86 patients. In another communication he states that thyroiditis occurred in 66 to 68 per cent. of his patients who suffered with acute articular rheumatism. Eleven patients with acute rheumatism presented thyroid enlargement with tenderness, with acute symptoms of intoxication; tremor of fingers, tachycardia, extra cardiac murmurs and throbbing of vessels, profuse sweats, etc. Vincent observed a subsidence of the thyroid swelling, tenderness and overfunction coincidently with convalescent stage of the rheumatism. Vincent apparently interprets the thyroid enlargement and overfunction to a reciprocal reaction of the body in defence of the rheumatic infection. He observes that in obstinate acute rheumatism with complications the thyroid may be only moderately enlarged and may quickly subside. He believes this explains the value of iodids in obstinate cases. He also thinks that the

salicylates are of value in reducing this type of thyroiditis. He reports the continuation of the thyroid enlargement with all the phenomena of exophthalmic goiter in several patients and in a few patients with rheumatic thyroiditis subsequent atrophy of the gland with the development of scleroderma and other symptoms of hypothyroidism. Sougues⁷, Albertin⁸ and Weintraud⁹ report similar observations of thyroid enlargement, tenderness and symptoms of hyperthyroidism in acute rheumatic fever.

None of these reporters mentions the probability of the thyroid enlargement and tenderness being due to the same rheumatic infectious agent of focal origin.

These reports and the meager personal experience noted in the cases cited aroused the interest of the clinic as to the possibility of focal infection as a cause of goiter. The following case-reports are interesting and seem to show that there is an infectious type of goiter with and without symptoms of exophthalmic goiter, which seems to be of focal origin. The rapid subsidence of the goiter and the symptoms after removal of the foci of infection in the jaws and tonsils was a surprise. Bacteriologic examination of the tissues and alveolar pus revealed mainly streptococci. Autogenous vaccines were used with one exception in all the patients. No drug treatment with the exception of iron, for one, was used.

CASE 4.—Mrs. C. F., married, aged 49, U. S., admitted April 30, 1914. Diagnosis: Exophthalmic goiter; tonsillitis chronica; abscesses alveolaris. Complaint: Frequent sore throat; goiter for two years; muscular tremor for one year, much worse recently; tachycardia for more than a year; dyspnea of exertion; nervous and emotional; gradual loss of weight; lessened strength and endurance. Menopause at 47. Examination: Skin pale, pseudoscleroderma of hands, forearms and forehead; eyes normal; no lymphadenopathy; large goiter, partially cystic; heart, left border dullness 11 cm., tones pure, rate 96 to 100; muscular tremor, fingers; many carious teeth with alveolar infection (roentgenograms); tonsils enlarged, fissured and infected; blood: reds 4,700,000, whites 7,800, hemoglobin 65 per cent.; urine, normal; blood-pressure, 130, systolic. Treatment: Tonsillectomy; extraction of all teeth; rest and plentiful food. Result: May 12, 1914, discharged much improved. Goiter diminished more than half; symptoms of hyperthyroidism practically nil.

CASE 5.—Miss J. L., aged 18, telephone operator, U. S., admitted May 2, 1914. Diagnosis: Exophthalmic goiter; tonsillitis chronica; abscesses alveolaris. Complaint: Goiter, nervousness and emotion; muscular tremor; tachycardia; dyspnea of exertion; loss of weight and strength; headache; hot flashes and profuse perspiration; tonsillitis and confinement to house for a week every winter. Duration of symptoms six years. Examination: Well-nourished and good color. No exophthalmos; tonsils large and infected; six molar teeth show alveolar infection (roentgenograms); a moderate symmetrical, firm goiter; heart normal, pulse 80 to 110; temperature subfebrile; tremor of fingers; blood, normal; urine, normal; blood-pressure 100 systolic. Treatment: tonsillectomy, extraction of teeth with infected roots, autogenous vaccination with strains of streptococci obtained from tonsils and dental canals. May 18, 1914, discharged to family physician. Goiter has disappeared. Symptoms of hyperthyroidism much improved. June 18, 1914, the family physician reports the patient in good condition of health.

CASE 6.—Miss M. W., aged 20, telephone operator, U. S., admitted May 12, 1914. Diagnosis: Exophthalmic goiter; tonsillitis chronica. Complaint: Goiter for unknown period;

rapid increase in size recently; tachycardia for year or longer; dyspnea of exertion; nervous and emotional; frequent subjective flashes of heat; prominence of eyeballs for a few weeks; loss of 15 pounds in weight in last few months; frequent sore throat; tonsillotomy three years ago. Examination: General pallor; moderate exophthalmos and lagophthalmus; tonsil stumps large and infected; teeth good, some dentistry; thyroid enlarged, symmetrical and firm; heart normal size, rapid, 100 to 120, somewhat irregular, tones pure, but snappy; tremor of extended fingers; reds, 3,300,000, whites 8,300, hemoglobin 60 per cent.; blood-pressure 125 systolic; urine, normal. Treatment: Tonsillectomy; rest; hematinics and plentiful food. May 20, 1914, discharged to family physician, much improved. June 18, 1914, family physician reports the patient much improved. Goiter much diminished in size. General condition excellent.

CASE 7.—Miss M. K., aged 24, telephone operator, U. S., admitted April 18, 1914. Complaint: Chronic arthritis of joints of fingers; frequent tonsillitis; goiter; occipitofrontal headache, fainting attacks and nervousness. Examination: Well-nourished; good color; tonsils large, fissured and infected; four lower teeth show alveolar infection (roentgenograms); swelling, soreness and stiffness of many joints of fingers; heart, lungs, urine and blood normal. No symptoms of hyperthyroidism. Treatment: Tonsillectomy, extraction of teeth with infected roots, autogenous vaccination with streptococci (*S. viridans* and *S. hemolyticus*) obtained from tonsils and dental canals. May 10, 1914, discharged much improved. June 6, 1914, returned and reported ability to return to work. Goiter practically disappeared. June 18, 1914, patient at work. Goiter about one half original size. General condition good. Arthritis of fingers much improved.

CASE 8.—Miss M. M., aged 21, telephone operator, U. S., admitted May 18, 1914. Diagnosis: Goiter; tonsillitis chronica. Complaint: Frequent sore throat, hoarseness; goiter of unknown duration, intermittent enlargement of lymph-nodes of anterior triangles of neck; nervous and emotional; lessened strength and endurance. Examination: Moderate exophthalmos and lagophthalmus; tonsils enlarged, fissured and infected; teeth, no visible infection, much dentistry; thyroid enlarged, chiefly the isthmus and right lobe; a few palpable submaxillary lymph-nodes; heart normal, 68 to 80; slight tremor of extended fingers; reds, 4,800,000, whites 10,300, hemoglobin 75 per cent.; blood-pressure 120 systolic; urine normal. Treatment: Tonsillectomy and rest. May 25, 1914, discharged to family physician much improved. June 18, 1914, family physician reports condition improved with the thyroid almost normal size.

CASE 9.—Miss E. S., aged 23, U. S., admitted May 19, 1914. Diagnosis: Exophthalmic goiter; tonsillitis chronica; impacted molar teeth. Complaint: At 17 became nervous and emotional, had tachycardia, loss of weight and strength, muscular tremor, moderate goiter, sweating, diarrhea, etc. Diagnosis of exophthalmic goiter and operation advised by home physician. Instead took rest cure. Improvement. Since then invalid with periods of improvement alternating with relapses. Now has tachycardia with irregular beating; nervousness, with hot flashes, insomnia and varying emotions; muscular tremor, generalized; profuse perspiration; diarrhea; occasional nausea and vomiting; weakness; loss of weight; exophthalmos and goiter. Had acute rheumatism at 12; sore throat on rare occasions. Menses irregular. Examination: Fairly nourished. Moderate exophthalmos; teeth, no caries, impacted molars (roentgenogram); tonsils large, buried, smooth exposed surfaces; thyroid visibly and palpably enlarged; heart, left border dulness 11 cm., rate 100 to 120, rhythm, somewhat irregular, tones pure; tremor marked; temperature range 98.6 F.; carbohydrate tolerance to glucose gm. 50.0 normal; urine normal; blood-pressure 140 systolic; reds 4,500,000, whites 9,000, hemoglobin 80 per cent. Treatment: Tonsillectomy. Removal of impacted teeth. Rest. June 3, 1914, discharged to family physician. Goiter and symptoms of hyperthyroidism practically disappeared. June 16, 1914, a letter from the patient's sister states marked condition of general improvement. She says patient expresses surprise at the disappearance of uncomfort-

able sensations which had existed so long that she had thought them natural phenomena.

CASE 10.—Miss G. O'B., aged 23, telephone operator, U. S., admitted May 20, 1914. Diagnosis: Exophthalmic goiter; tonsillitis chronica; abscess alveolaris; anemia secondary. Illness began one year ago with severe tonsillitis. Soon noticed goiter with extreme nervousness, muscular tremor, tachycardia and a complete nervous collapse in March, 1914. Examination: Well-nourished; pale; nervous; marked muscular tremor; no exophthalmos; symmetrically enlarged thyroid gland; three carious teeth with alveolar infection (roentgenogram); infected faucial tonsils; subfebrile temperature; pulse 96 to 130, heart-tones normal; blood: reds 2,580,000, whites 13,600, hemoglobin 40 per cent.; blood-pressure 125 systolic; urine normal. Treatment: Tonsillectomy; extraction of teeth with alveolar infection; hematinics; rest and good food. Result: Rapid improvement in goiter and symptoms of hyperthyroidism. June 18, 1914, patient continues to improve in a general way. Anemia less. Goiter still palpable, but symptoms of overaction of thyroid practically gone. This patient is the only one of the series of women who has not received vaccines.

No thyroid gland tissue was examined. Dr. E. C. Rosenow has recently made cultures from the deep tissues of many goiters, removed surgically in the treatment of exophthalmic goiter. Without exception he has been able to isolate and grow a streptobacillus of characteristic qualities. He is making experiments with the organism by animal inoculation and will make a report soon.

Farrant¹⁰ has investigated the pathologic changes of the thyroid in disease. He finds that certain microorganisms and certain toxemias may cause either a chronic hyperplasia with colloid or a complete acute hyperplasia. In the acute type the *B. aerogenes capsulatus*, *B. diphtheriae*, *B. dysenteriae* (Asylum, Shiga and Flexner types), *B. anthracis*, *B. tuberculosis*, *B. mallei*, bacillus of tetanus, *Micrococcus catarrhalis*, *Spirochaeta pallida*, *Plasmodium malariae*, chronic nephritis, cirrhosis of liver and toxemias due to abrin, ricin and diphtheria toxin produced rapid hyperplasia. Animal inoculation and examination of animal and human thyroids were the basis of the report.

In the chronic type, the coliform bacillus (chr.) tuberculosis, chronic, Malta fever, syphilis, actinomycosis, acute poliomyelitis, rheumatic fever, scarlatina and pernicious anemia were associated with thyroid enlargement. Involution of the thyroid followed the subsidence of the systemic disease.

That Farrant should not find acute hyperplasia in rheumatic fever is probably due to the absence of clinical observation.

THE WIDER APPLICATION OF THE ETIOLOGIC IMPORTANCE OF FOCAL INFECTION

To the now well-known relation of focal infection as a chief factor in the etiology of acute rheumatism, chronic deforming arthritis, gonorrheal arthritis, malignant endocarditis, myositis, myocarditis, septicemia of various bacterial types, tuberculosis, nephritis and visceral degeneration, we may add certain infectious types of thyroiditis, with or without hyperthyroidism, pancreatitis acute and chronic, with or without resulting glycosuria, peptic gastric and duodenal ulcer and cholecystitis.

With the defenses of the body diminished by overwork, exposure to cold, dissipation, insufficient or improper food, unhygienic surroundings, injuries from

10. Farrant, Rupert: The Pathological Changes of the Thyroid in Disease, Brit. Med. Jour., Feb. 28, 1914, p. 470.

former disease, (valvular scar) or trauma, the individual may suffer from acute rheumatic fever, chronic arthritis, myositis, chronic infectious endocarditis, pneumonia, ulcer of stomach, cholecystitis or pancreatitis, respectively dependent on the phase of mutation in pathogenicity, and affinity of the strain of the streptococcus-pneumococcus group in the focus of infection. These principles are important because proper management may (a) prevent the systemic disease and (b) guide one in the proper treatment of the systemic disease. The recognition and removal of chronic foci anywhere in the body is imperative as a prevention of progressive ill health. Emphasis should be made of chronic alveolar abscess, often unrecognized by the patient. Film roentgenograms of the jaws is often the only means of recognition. A pathologic tonsil is a menace and should be wholly removed. Chronic cholecystitis and chronic appendicitis should be promptly treated surgically. Chronic sinusitis may exist for years and finally be an important factor in the development of systemic disease. Following the removal of the focal infection, adequate individual and general hygiene will improve the body defenses and health will be maintained.

The removal of the focus of infection is demanded as a fundamental principle, in the treatment of the systemic diseases especially of the chronic type. Thereafter the management must be individual, based on the character and location of the infection. The attempt to immunize the patient against the infection must be attempted by restorative measures—food, pure air, passive and active graduated exercise, hematinic and other tonics, optimistic surroundings, etc. Autogenous vaccines may be used with rational reservation.

122 South Michigan Boulevard.

THE NEWER BACTERIOLOGY OF VARIOUS INFECTIONS AS DETERMINED BY SPECIAL METHODS *

E. C. ROSENOW, M.D.

CHICAGO

The bacteriology of most infections as worked out heretofore is largely the bacteriology of the fluids of the body and semifluid exudates. In acute infections a bacteriologic study of the fluids commonly yields trustworthy results, but in many chronic conditions the cultures are usually sterile and demonstration of bacteria in the tissues usually fails.

In this short paper I wish to describe methods for making cultures particularly from excised tissues and from the blood and other fluids in which due regard is paid to the question of oxygen pressure, particularly in the primary culture, and to detail very briefly the results obtained by their use in various infections.

PREPARATION OF THE EMULSION FROM THE TISSUES

The tissues are excised with strict aseptic precautions usually under local anesthesia and cultures made at once, a portion being reserved for microscopic study. In addition to the great care used to avoid contamination from skin or air the surface of the part used for cultures is sterilized by dipping it into boiling water, or even better, into a vigorous Bunsen flame,

or seared with a hot blade, then rapidly cooled in sterile salt solution and emulsified in the specially devised sterile air-chamber or "tissue-crusher" shown in the accompanying illustrations. The amount of heat used is determined by the size of the tissue at hand. Whenever possible, pieces of tissue at least 2 to 3 cm. in diameter are used for cultures.

The chamber (Fig. 1) is somewhat similar to the one already described¹ except that it contains a larger mortar and a small-sized meat-chopper.² It consists of an air-tight tin can (19 by 23 cm.) containing a large (10 cm.) hole on one end with a flanged rim to which is tied a long-sleeved, heavy, fleece-lined canvas glove; there is a smaller side opening (3 cm.) which is plugged with cotton and a large opening (8 by 12 cm.) at the top which is covered with mica and held in place by circular wires and surgeons' adhesive plaster. The meat-chopper is held in place through a hole at the farther end through which the shaft extends and a hole at the bottom through which a thumb-screw fits whereby it is clamped to a wood extension, fastened to a semicircular wood board nailed to the end. On the inside is fastened a suitable-sized tin can which serves as the mortar holder. The container without the meat-chopper answers very

Fig. 1.—Sterile air chamber. The right hand is used inside the apparatus.

well for small or relatively soft tissues, such as the lymph-glands in arthritis, while the one containing the meat-chopper is preferable for emulsifying larger and firmer tissues such as the thyroid gland, cystic ovaries and the glands in Hodgkin's disease. Sterilization is done in dry heat at 160 C. (320 F.) for one hour. For actual use the right hand and forearm are thoroughly scrubbed with soap and water and soaked in 1:1,000 mercuric chlorid and then introduced into the container and glove. Alcohol should not be used in sterilizing the hand because the vapors are apt to ignite with explosive violence when the side opening is flamed after removing the cotton plug; the mouth of the tube or bottle containing the tissue is flamed and held near the small opening in the side and the tissue grasped with long sterile forceps, and with the least possible exposure to the room air, inserted into the container and either cut into small pieces with the scissors or passed through the meat-chopper. Great care is exercised at all times not to move the gloved hand in or out of the container while the cotton plug is removed.

* Read before the Section on Practice of Medicine at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

¹ From the Memorial Institute for Infectious Diseases.

1. Rosenow: *Centralbl. f. Bakteriol., Orig.*, 1914, lxxiv, 366.

2. The meat-chopper is an inexpensive commercial article designated the "Baby Masticator" and manufactured by the Enterprise Manufacturing Company, 176 North Dearborn Street, Chicago.

After grinding the tissue in the mortar for a time, sterile quartz-sand and the emulsifying fluid, usually dextrose broth, are poured into the mortar through the side opening from thoroughly flamed test-tubes. The cotton plug is reinserted and the emulsifying process is continued. The emulsion when completed is poured into a thoroughly flamed test-tube or graduate of suitable size, inserted through the side opening.

In attempting to simplify as much as possible the emulsification of tissues and to check up the results obtained with the sterile air-chamber, the "tissue-crusher" (Fig. 2), a modification of the method used by Hirschfelder to obtain tissue juice, was devised. It consists of two close-fitting threaded metal tubes; the outer tube is fitted with an air-tight removable bottom, the inner surface being made rough, and a four-sided rim, while the inner tube is fitted with a removable disk containing numerous very small drilled holes and a handle which serves as a wrench. The inner tube is plugged with cotton and placed inside

Fig. 2.—Tissue crusher.

the other and the instrument sterilized in hot air. In order to prevent leakage the thread of the inner tube should be covered with hot sterile paraffin or petroleum oil just before using. The tissue is placed in the outer tube and the inner tube turned in the outer, using the necessary force until the tissue is crushed and expressed into the inner tube. The instrument is now held slantwise, the cotton plug flamed and removed, the emulsifying fluid added and the emulsion transferred to a sterile test-tube with a sterile pipet.³

METHOD OF PREPARING THE BLOOD-CULTURES

In order to furnish bacteria from the blood and other sources a gradient of oxygen pressure, the following method for making blood-cultures has been used with good results: From 15 to 30 c.c. of blood are

withdrawn from the vein at the bend of the elbow in the usual way and decalcified, by adding it to a solution of 2 per cent. sodium citrate in sodium chlorid solution in the proportion of 5 c.c. of blood per 1 c.c. of solution. Control tests have shown that the bacteria contained in the blood from a wide range of conditions live in this solution for at least seventy-two hours. The citrate solution is kept in a tube of suitable size closed by an aluminum screw-top containing a rubber disk and sealed with paraffin. This may be used at the bedside and then sent to the laboratory for cultures in case, for some reason, it is not convenient to make the complete culture at the bedside. In my work a portion of the citrated blood has been at once planted and the remainder added by means of a sterile pipet to sterile distilled water contained in bottles which serve as centrifuge tubes, there being at least 10 parts of water to 1 part of citrated blood. This is centrifuged at once and the supernatant hemoglobin containing water is poured off or the sediment removed with a sterile pipet, and planted. The sterile water serves as a means of getting rid of the hemoglobin and the serum. Control tests with the serum after the corpuscles have separated by gravity show that in the aerobic cultures the inhibiting action of the hemoglobin is more marked than that of the serum; in fact, the serum is a desirable constituent in streptococcal cultures. Hence in suspected streptococcal infections the serum and the sediment of the dissolved corpuscles may be planted separately. In some instances the hemoglobin has been converted into methemoglobin by passing carbon monoxid (illuminating gas) through the decalcified blood by means of a sterile pipet containing a long sterile cotton plug.

THE PREPARATION OF THE CULTURES

The emulsion of the tissues or the sediment of the dehemoglobinated blood is inoculated in the way best suited for the particular case at hand. Shake-cultures in tall columns (10 to 20 cm.) of ascites dextrose (1 per cent.) agar and plain agar (0.5 to 0.8 per cent. acid to phenolphthalein) with or without serum have yielded the best results. The ascites fluid is collected in a sterile manner and heated on successive days to 60 C. (140 F.) for one hour or for twenty-four hours and used only after the sterility has been determined. To 9 parts of 0.5 per cent. agar, prepared from Liebig's extract of beef and Witte peptone, 1 part of ascites fluid is added with a sterile pipet after the agar is either thoroughly boiled in a bath or steamed in an Arnold sterilizer for at least fifteen minutes to drive off molecular oxygen, and cooled to 60 C. The emulsion or other material is added to the agar when cooled to 39 C. (102.2 F.) by inserting the mouth of the pipet to the bottom and forcing out its contents while the pipet is withdrawn. After the cotton plug is flamed and replaced in the test-tube the further mixing is accompanied by partially inverting the tube once or twice. Care is exercised not to blow bubbles of air through the agar.

Owing to the oxygen-consuming power of living cells the bottom of the tubes is rendered anaerobic while the top necessarily remains aerobic, and the space between represents a gradient of oxygen pressure between the two extremes. In order to bring about a still greater range of conditions in view of the consideration that the emulsion or tissue juice may be bactericidal or may favor the growth of the bacteria,

3. The sterile air-chamber may be made in the laboratory, while the tissue-crusher requires a well-equipped machine-shop for its construction. Both may be purchased from V. Mueller & Co., 1779 Ogden Avenue, Chicago.

only a small amount of emulsion is added to some tubes and a large amount to others. In the case of the blood-sediment or joint fluid when only a small amount is at hand, pieces of sterile rabbit or guinea-pig tissue are added to the bottom of the tube if strict anaerobic conditions are desired. A gradient of H and OH ions in the mediums, obtained by superimposing a plus 1 agar or a minus 1 agar and vice versa has also been found useful in some conditions.

Plain serum or ascites, agar and broth, ascites-dextrose-broth in tall tubes, enriched ascites fluid, with or without sterile tissue the surface of Loeffler's serum, plain and dextrose blood-agar slants and plates, kept under aerobic and anaerobic conditions, and at times litmus-milk and ox-bile, and in Hodgkin's disease Dorset's egg mediums are also inoculated. These, while not as favorable culture mediums, have yielded positive results in isolated instances when the shake-cultures in agar were negative. The cultures are incubated at 37 C. for ten to fourteen days before they are discarded. The tubes of dextrose-agar are carefully examined for colonies in a strong light. Smears are made from the water of condensation of the Loeffler's serum and blood-agar slants, of the liquid cultures if turbid and of the sediment always, and from the bottom of the tube of agar even though no colonies are found. Colonies in the depths of the dextrose-agar are examined by breaking the tube cross-wise by means of a glass cutter and a red-hot bead at the end of a glass pipet, the surface of the tube being sterilized in the flame just before breaking it. If a positive result is obtained, at least one of the subcultures is made in such a way as to reproduce as nearly as possible the conditions under which the original growth was obtained. This point is particularly important with those strains which show a preference for anaerobic conditions. Search for unknown bacteria was made in smears stained in various ways from the cut surface of the glands and various emulsions and from the depths of the cultures both by staining and with the aid of dark-field illumination.

RESULTS

By this method, which is similar to those employed by Theobald Smith and Noguchi but in which there is afforded not only aerobic and anaerobic conditions but a gradation of oxygen pressure between these two points, a gradation of H and OH ions, and a wide range of nutrition, positive cultures have been obtained frequently while cultures made in the usual way remained sterile.

Thus certain non-hemolyzing streptococci have been isolated from the blood repeatedly when the usual method failed or showed much fewer colonies; in leukemia this has happened as long as four months before death; in rheumatic fever during the height of the disease in 5 of 9 attempts; in peliosis rheumatica in 2 cases, and occasionally from arthritis deformans. Hemolytic streptococci were obtained from three cases of puerperal sepsis; the *Streptococcus viridans* in two cases of chronic infectious endocarditis, while the results of the usual cultures suggested the "bacteria-free stage" (Libman) of the disease. Diphtheroid-like organisms have been isolated from the blood during the febrile period in four cases of Hodgkin's disease, and the same organism from the blood as from the nodes in two of three cases of erythema nodosum in which blood-cultures were made. Diphtheroid bacilli

have been isolated from the blood in four cases of severe infections resembling rheumatism; the *Bacillus aerogenes capsulatus* (*B. welchii*) from the blood in one case of bronchopneumonia, one case of acute rheumatism, and in leukemia.

Streptococci corresponding to those which I have isolated previously from the joints have been isolated from glands draining the involved joints in twelve cases and *B. welchii* alone or in conjunction with streptococci in four of twelve cases of acute articular rheumatism.

In 54 cases of arthritis deformans one or more glands draining the joints have been examined in each case. Non-hemolyzing streptococci producing usually no distinct green on blood-agar plates and often showing a marked preference for anaerobic conditions in the primary culture but otherwise resembling *Streptococcus viridans* have been isolated 32 times; staphylococcus 5 times; an organism resembling *B. mucosus* 3 times, *Micrococcus catarrhalis* and the gonococcus once each, *B. welchii* in 14 cases, and diphtheroid bacilli in 5 cases. In 7 cases the cultures remained sterile. In both rheumatic and deforming arthritis the same organisms have been isolated simultaneously from the fluid or capsule of the joints and the excised gland.

A diphtheroid bacillus showing a wide range of preference for oxygen in the different cases has been cultivated in all of some 40-odd cases of Hodgkin's disease; a staphylococcus in 17; *Streptococcus viridans* in 7; *B. welchii* in 14, and an unidentified Gram-negative motile bacillus in 6 cases.

A non-hemolyzing, sometimes green-producing (blood-agar) streptococcus has been obtained from the depth of the tissue in 16 of 21 chronic indurated duodenal and gastric ulcers, and from the small glands adjacent to the ulcer in 4 of 5 cases. A staphylococcus-like organism was present usually in smaller numbers in 16; *Staphylococcus aureus* only once. The base of the ulcers was either entirely sterile or contained only a small number of bacteria and yeast-cells. The number of colonies of streptococci was roughly proportionate to the gross or microscopic evidence of inflammation. Only one perforating ulcer was examined and this showed the largest number of colonies of streptococci. The negative results obtained were in ulcers which seemed to be practically healed. *B. welchii* was isolated from the ulcers in 6 cases and from the adjacent glands in 3. Three ulcers showed diphtheroid bacilli, 4 yeast-cells, and in a number there were found a few colonies of a large Gram-positive aerobic bacillus, probably belonging to the *subtilis* group. The colon bacillus was found only once in the simple ulcers excised at operation, but was present in large numbers in one examined shortly after death and in small numbers in two out of three ulcers the seat of carcinoma.

Streptococci quite similar to those from the ulcers have been isolated in pure culture from the excised tissue of the gall-bladder in cholecystitis in one case and from the center of gall-stones in 4 of 7 cases. *B. welchii* and *B. coli* were found together with the streptococcus in the gall-stones in one case and a bacillus resembling closely the typhoid bacillus in another.

A polymorphous, sometimes clubbed, diplobacillus was obtained in pure culture from excised nodes in each of 7 cases of erythema nodosum; from a cervical lymph-gland draining an infected tonsil in one case

and in mixture from the focus of infection (tonsil and superficial ulcer on anterior pillar) in 2 cases of erythema nodosum.

An anaerobic Gram-positive diplobacillus-like organism has been isolated from the thyroid gland removed at operation in 25 out of 32 cases of goiter (mostly exophthalmic goiter) in man, from the blood on two occasions in a severe case of exophthalmic goiter, and in conjunction with Dr. Moon, in 8 of 12 dogs having goiter. We failed to obtain the organism from the gland in six of seven dogs showing apparently normal-sized thyroid glands, while one showed a few colonies. *B. welchii* was found in all but 6 of the thyroid glands examined. Three of these were normal glands in dogs. A staphylococcus which usually produces hemolysis on blood-agar and grows unusually well anaerobically was found in most of the goiters in those from both man and dog. It is as yet impossible to state whether or not this coccus comes from the skin, although it perhaps does not. Non-hemolyzing streptococci have been isolated in 3 goiters from man and in 2 goiters from dogs.

Cystic ovaries from 25 patients have been examined by this method. Streptococci, often good green-producing, have been found in pure culture in 14, in some instances, both from the cyst fluid and the emulsified tissues; but the cyst content is usually sterile. A partially anaerobic diplobacillus resembling quite closely the organism from the thyroid gland has been found in 4; staphylococci in small numbers in 3; *B. welchii* in all but 5 cases.

SIGNIFICANCE OF THE FINDINGS

The common localization and lesions produced on intravenous injection of streptococci soon after isolation from acute rheumatism, from arthritis deformans, from ulcer of the stomach and from the tissue of the gall-bladder in cholecystitis and the center of gall-stones, together with other facts, suggests strongly that they are not secondary invaders but the important etiologic factor in each of these conditions because the strains from rheumatism commonly produce arthritis, endocarditis, myocarditis and pericarditis; the strains from arthritis deformans, arthritis and myositis but rarely endocarditis or pericarditis; the strains from the depths of ulcers of the stomach often show a striking affinity for the mucous membrane of the stomach and duodenum (dogs and rabbits); while those from the gall-bladder and the center of gall-stones commonly produce cholecystitis. The bacillus isolated from erythema nodosum when injected as isolated showed a marked affinity for the subcutaneous tissue in dogs, rabbits and guinea-pigs, producing localized hemorrhages followed by infiltration resembling the nodes seen in man, the lesions often being symmetrically placed usually near a relatively large blood-vessel. On artificial cultivation and on animal passage the strains lost this peculiar property. In both instances the organism tended to become a streptococcus and on passage it acquired an affinity for the joints, fascia, muscles and endocardium. This fact would seem to afford an explanation of the common occurrence of arthritis and sometimes endocarditis in erythema nodosum and allied conditions.

The almost constant presence of diphtheroid organisms in the glands and their demonstration in the blood in Hodgkin's disease in conjunction with the results of experiments on monkeys by Bunting and Yates and

by Negri and Mieremet, and the good results obtained in some cases by the use of autogenous vaccines suggest strongly that these organisms play at least a prominent rôle in this disease; but the fact that other organisms are commonly found also and that diphtheroid bacilli indistinguishable from some of the strains from Hodgkin's disease are found in many other conditions compels one to wait for more experimental evidence before concluding that these bacilli are the real cause of Hodgkin's disease.

The etiologic rôle of infection in goiter is becoming more apparent; enlargement of the thyroid gland has been noted in various infections, particularly in rheumatism; and the peculiar distribution of endemic goiter, and other clinical facts, suggest that the cause of simple and exophthalmic goiter may be due to an infection. The symptoms and the enlargement of the gland, however, have usually been considered toxic in nature and not due to localization of the bacteria in the gland. No one, as far as I can learn, has isolated an organism from the thyroid in a series of cases. The fact that the same organism has been isolated from goiters in both dogs and man, and in the latter apparently in proportion to the degree of symptoms and from the blood, the absence of this organism in normal thyroid glands in dogs, the fact that it lives longer in the thyroid gland than in the kidney and other tissues of dogs following intravenous injection, and that goiter has appeared in two dogs after intravenous injection of this organism, suggest that goiter may be due not only to toxins produced in other regions of the body but to an actual localization in the gland of bacteria. Studies of the chief organism found show that it is probably closely related to the streptococcus group and this may explain why thyroid enlargement is observed commonly in rheumatism and in cases having foci of infection in which the predominating flora is streptococcal.

The significance of the findings of the streptococcus in cystic ovaries is not yet clear. Further experiments on animals are necessary and the immunologic reactions in the various conditions, particularly in goiter and cystic ovaries, need to be worked out before definite conclusions can be drawn. It may be that the organisms isolated are merely secondary invaders. The rather frequent occurrence of diphtheroid-like organisms in the tissues and blood during life is, I believe, significant. They are probably not wholly secondary or harmless invaders.

Altogether the *B. welchii*, or an organism closely related, has been isolated from various tissues in man 103 times and from the blood or joint fluids six times. It has frequently been found in various tissues, such as the thyroid, muscle and kidney of dogs and occasionally in livers of rabbits and guinea-pigs. On account of this surprising finding and because the organism is an anaerobe and spore-bearing, every possible source, especially the serum and ascitic fluids, other than the tissue inoculated has been excluded by control-tests. The common presence of this organism in the tissues of man and the dog (carnivorous animals) and its absence in the rabbit and guinea-pig (herbivorous animals) is, I believe, of significance. It exists in the tissues probably chiefly in the spore form and the growth usually does not result except when the oxygen pressure has reached a certain grade. The fact that the strains grow readily at a certain grade of oxygen pressure without production of gas and that

they produce the characteristic growth with gas formation only under strict anaerobic conditions suggest that under special circumstances (a lowered oxygen pressure, increased virulence or growth in symbiosis with other bacteria perhaps) *B. welchii* may not be an entirely harmless invader.

Finally, whatever the ultimate significance of these findings may prove to be, the common isolation of bacteria from tissues which have been considered sterile is of definite importance, lends support to the contentions of Adami and others that certain ill-understood conditions are due to a low-grade infection and not merely intoxication and calls for an extensive study of the whole question by this or similar methods.

I wish to express my very great appreciation to the numerous physicians, particularly Dr. Billings, who have supplied me with material. The more complete reports are to appear in the *Journal of Infectious Diseases*.

629 South Wood Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. BILLINGS AND ROSENOW

DR. WILLIAM S. THAYER, Baltimore: There has been no one circumstance in the last fifteen years that has so changed the aspect of the practice of medicine as the recognition of the influence of local foci of infection on the production and course of a variety of general processes of previously uncertain etiology. In the discussion on cardiac disease, Dr. Cabot, in his classification, referred to the "rheumatic" cases, stating that although the term was rough and general, it yet covered those infections which are commonly associated with arthritis as well as cardiac disease. It is well to emphasize this association. When one meets to-day a mitral stenosis or insufficiency he proceeds in a very different way from that in which he did twenty years ago. One's first thought now should be to search for a focus of chronic infection by the removal of which the probability of progression of the malady may be greatly reduced. The proportion of cases of valvular disease of uncertain origin that show old chronic affections of sinuses, of teeth, especially of the tonsils, is very large. I would emphasize also that in tonsillar operations it is most important that the operation be complete. In a very large number of patients who come to me with the statement that their tonsils have been removed, it is easy to demonstrate that most of the lower pole of the tonsil is still present, the crypts often sealed by cicatricial tissue and more dangerous perhaps than before operation. Even in the hands of men whose technic is very good it is not uncommon to see in young people a hyperplasia of small islands of lymphoid tissue which remained after operation. These little islands may later be infected and give rise to all the symptoms formerly experienced.

DR. A. C. GRIFFITH, Kansas City, Mo.: It has been my good fortune since the discovery of the diphtheroid bacilli to see a few cases of Hodgkin's disease. One case in particular occurred in an elderly lady who had been suffering for six or seven years with glandular enlargement. We removed one of these glands and developed the diphtheroid bacillus; also a coccus. Dr. Rosenow has described their clinical characteristics. These organisms are mostly of the aerobic type. The patient was put on autogenous vaccines made from the growth of the organism. The treatment was given in gradually increasing doses until the swelling of the glands began to disappear and the patient was doing nicely. She, however, was persuaded to take up Christian Science. Two weeks later I was called in when she was dying from overinfection or intoxication as a result of the activity of the glands. Necropsy showed that the changes in the glands were those characteristic of Hodgkin's disease; there was the degeneration and softening in the center and the outer harder portion. We used the vaccines three hundred millions to the cubic centimeter. I started in with 0.5 c.c. and

increased the dose to 2 c.c. I gave first a dose every three or four days and toward the last 2 c.c. every other day, and the glands were disappearing when the patient left me to follow one of the cults.

DR. FRANK SMITHIES, Chicago: In the study of the histories of nearly ten thousand cases of gastro-intestinal trouble I have been struck by the fact that aggravations of the disturbances were quite common in the spring and the fall. It will be especially noted that this happens in the case of peptic ulcer. It will also be recalled that these seasons of the year include the periods during which epidemic infectious diseases are most prevalent. In view of Dr. Rosenow's investigations, infection of the gastric mucosa by micro-organisms might occur at these periods during the course of the disease. In the case of ulcers already existing, reinfection may occur and the process be lighted up. The acid reaction of the stomach is no criterion of its bacterial cleanliness. I have shown this by my study of the findings in more than 7,000 consecutive test-meals. In the majority of the gastric-ulcer cases, there is a possibility of finding foci of infection elsewhere. Studying 1,500 peptic ulcers, I find that in more than 60 per cent. coincident or earlier infection of the gall-bladder or appendix could be noted. In cases of cholecystitis, with or without stones, there was pancreatitis in 12.5 per cent., and in common-duct obstruction, pancreatitis was noted in more than 28 per cent. of instances. It should be emphasized that cleaning up a local focus, as in the mouth, does not guarantee that patients will recover from damage that has already been done in the extensive area of the gastro-intestinal tract.

DR. E. LIRMAN, New York: The occurrence of exacerbations in cases of duodenal ulcer following so-called colds has been particularly emphasized by Hershell of London. In trying to establish a diagnosis between duodenal ulcer and cases of functional disturbance a history of such occurrence is of value. I was interested in Dr. Rosenow's statement that he is not willing definitely to accept the organism described in connection with Hodgkin's disease as being the cause of the disease. Dr. Celler has made a study of a number of cases of various forms of diseases of lymph-nodes and has found the bacillus not only in cases of Hodgkin's disease, but also in other diseases of the lymph-nodes, and particularly in two cases of typical tuberculosis. Apart from that, the *Streptococcus viridans* has been found in lymph-nodes in cases of Hodgkin's disease as well as in other lymph-nodes. Complement-fixation tests made by Dr. Olitsky in cases of Hodgkin's disease have proved to be absolutely negative in all instances. These findings lead us to be careful before accepting the organism as being the etiologic factor in the disease and make us keep in mind the question of latent microbism. There is no doubt that Dr. Rosenow has produced definite mutations in the streptococcus-pneumococcus group. As regards Dr. Rosenow's statement that the organisms from a certain type of infection cause, at least for a time, the same lesions in animals as in man, some work done by Drs. Rothschild and Thalheimer indicate that exceptions occur. They succeeded in 50 per cent. of the inoculated animals, in producing arthritis with recently inoculated strains obtained from cases of subacute endocarditis in man. Pericarditis has been found in animals inoculated with the same organisms and this is a very unusual phenomenon in the disease from which the organisms are obtained.

DR. JAMES M. ANDERS, Philadelphia: These two papers rivet the attention of the profession especially on the head as the seat of infective foci. It has long been well understood that in the case of acute miliary tuberculosis invariably an old focus exists somewhere in the body, most frequently in the lungs, from which the tubercle bacilli come. These papers emphasize the importance of a careful inspection of the mouth and throat as a part of our routine examinations of patients. If foci of inflammation are found there, they should, of course, be energetically attacked without delay. It is important to recollect that if removal of such focal infections fail to bring about a cure of the condition from which the

patient may be suffering, it is not evidence to the contrary, but means, as pointed out by Dr. Billings, that hematogenous metastasis has already taken place. The American Medical Association has its Section on Stomatology, and it would be entirely proper, it seems to me, for the Section on Practice of Medicine to urge, through the House of Delegates the establishment of chairs of Stomatology in our medical colleges.

DR. DE LANCEY ROCHESTER, Buffalo, N. Y.: I wish to speak of focal infections especially of the teeth and tonsils. In three cases having teeth infections accompanied by endocarditis in which there were no manifest symptoms in the mouth, but in which the Roentgen ray showed an abscess at the roots of the teeth, when the abscess was removed the symptoms subsided and the patients improved clinically. The organism found was the ordinary streptococcus pyogenes. I have had four cases which have impressed on me the importance of having the tonsils completely removed in cases of infection. The danger of an incomplete operation is illustrated in one case in which the toxic process had gone too far before the trouble was recognized. The patient was a woman who gave a history of rheumatism, multiple arthritis and endocarditis which had been treated in the hospital for two weeks. She improved under the salicylates and got up. Later she had a recurrence, ushered in with a temperature of 104.5 F. and her pulse was uncountable. She gave a history of having had a tonsil operation ten years before. There was also a history of sore throat and an exudate over the tonsils. The condition of the patient was so serious that she could not be operated on. She died of severe systemic toxemia, in all probability due to infection from the tonsils.

DR. ALFRED STENGEL, Philadelphia: Dr. Rosenow's statement with regard to the cause or the part played by the organism in Hodgkin's disease was very conservative. He said that we are not sure of the relation of the diphtheroid organism to Hodgkin's disease, but it seems to me that we are sure that this organism is the specific organism of Hodgkin's disease. I have only four cases of such infection to report: one of endothelioma; chronic simple inflammation of the glands; one of lymphoid enlargement in a patient with rheumatoid arthritis, and lastly another rheumatoid case not easily classified.

DR. J. BIRNEY GUTHRIE, New Orleans: Has Dr. Rosenow applied his technic in finding the cause of the short fevers of obscure origin in children, which are accompanied by lymphatic enlargement—the so-called glandular fevers? These symptoms of unexplained fever and lymphatic enlargement are quite common in children and it would be interesting to have this method applied to their investigation.

DR. HARVEY D. WOOD, Fayetteville, Ark.: Owing to the rapid progress that has been made in our knowledge of the cause of inflammation and infection, I believe the time has come when the definition of the termination "itis" should be made to include infection as well as inflammation. Since listening to Dr. Billings' paper and the following discussion I have been more than ever fully impressed with the need of a more comprehensive definition of this termination. The phenomena of seasonal recurrences and exacerbations of ulcer, due to infection, have been so clearly set forth in this discussion that it gives us a better understanding of many pathologic processes. The infection that comes from the bite of the infected bedbug is now thought by some, who are doing special work on this line, to be the cause of pellagra. This disease has its period of exacerbation in the spring-time, when this pestiferous insect begins to get busy. Should this prediction prove to be the true source of the pathology of this disease, there are many persons whose minds will be relieved from the fear of having this malady.

DR. FRANK BILLINGS, Chicago: In our group of workers we know that Dr. Rosenow is dependable. He has an opportunity to study disease clinically. The diphtheroid bacillus has been successfully cultivated from the enlarged lymph nodes of about forty, and from the blood of five patients with Hodgkin's disease. These five had fever. The histology

of the glandular tissues varied from typical Hodgkin's to simple lymphocytomas, lymphosarcoma and tuberculosis. In one lymphosarcoma the organism could not be cultivated. Many of these patients have received the autogenous vaccine subcutaneously in the dosage of 10,000,000 to 1,500,000,000 usually repeated once a week. Two have received the vaccine in large doses intravenously. Used subcutaneously there is no recognizable general reaction. Intravenously, general reaction has been noted; fever, rapid pulse, general discomfort, headache, etc. Practically all patients have also been treated with efficient roentgenization. In the chronic non-febrile cases the vaccines and roentgenotherapy seem to produce better results than the Roentgen ray alone. We are now preparing a report on the series of patients. Dr. I. Hektoen will report the histopathology of the glands, Dr. Rosenow will give the bacteriology and I shall prepare the clinical data. We are now attempting to immunize a horse with mixed strains of the diphtheroid bacillus. If successful we shall add the serum to the treatment.

DR. E. C. ROSENOW, Chicago: One word as to the importance of foci of infection other than those of the mouth. I recently saw a patient in Dr. Billings' service who had rheumatic endocarditis, pericarditis, etc., which apparently was the result of an infected ingrowing toe-nail. The toe was operated on, the streptococcus isolated and the disease reproduced in dogs and rabbits. Another patient had severe rheumatism including pericarditis and endocarditis which began ten days after a crushing injury of the thumb. Again the disease was reproduced with the streptococcus isolated from the wound on the thumb. I am sorry that I am not prepared to say what the cultures of the glands show in the short fevers in children with glandular enlargement. I believe that the glands in these cases contain bacteria which are the cause of the disease. Streptococci were isolated from the glands in seven of the cases of Hodgkin's disease. It is quite well known that ulcers heal more quickly in the cardiac end of the stomach than in the pyloric end or duodenum. This is generally believed to be due to mechanical causes, but if streptococci play a rôle in the etiology of ulcer, as seems likely, why might not this be due in part to a greater bactericidal power of the mucous membrane of the former because acid-secreting, than that of the pylorus and duodenum in which no acid cells are present? The infectious nature of ulcer would best explain the seasonal exacerbations and the recurrences which come without known cause, the recurrences taking place when the immunity of the blood from a previous attack has disappeared. The most important factor in the management of ulcer of the stomach—the recognition and removal of various foci of infection—has been overlooked in the past. Proper regard of this point should reduce the incidence, percentage of recurrences and earlier healing of ulcer of the stomach and duodenum.

Good Roads Prevent Disease.—Few persons, on first thought, would see any possible connection between good roads and good health. Yet the State Board of Health of Kansas says that good roads can and will prevent disease. How? By the removal of weeds and trash. Weeds and trash prevent the prompt evaporation of moisture and promote retention of ground water. These make ideal breeding spots for mosquitoes, flies and other disease carriers. . . . Good roads also prevent disease by providing good drainage. Many farms have no means of drainage except by ditches along roadways. Open ditches, clear of brush and debris, with hardened surface and proper fall, afford these farms the opportunity of ridding themselves of many a stagnant pool. . . . Road-oiling in itself is destructive of insect larvae, especially mosquitoes—a well-known fact. Dry roads offer pedestrians and notably children who are compelled to walk to and from school, dry shoes and feet. . . . Good roads are active disease prevention agencies, aside from their financial and commercial value.—*Monthly Bull. Ohio State Board of Health.*

GASTRO-INTESTINAL STUDIES

II. THE FRACTIONAL STUDY OF GASTRIC DIGESTION
WITH A DESCRIPTION OF NORMAL AND
PATHOLOGIC CURVES*MARTIN E. REHFUSS, M.D., OLAF BERGEIM, Ph.D.
AND
P. B. HAWK, Ph.D.
PHILADELPHIA

For years the experiments of Pawlow¹ and his school seemed to be the last word in the study of digestion, and the results which they obtained on dogs with fistulas and lesser sacs were unqualifiedly applied to man. With the exception of comparatively isolated instances such as that of Alexis St. Martin and others, the only information regarding the human stomach was obtained by means of the stomach-tube and Roentgen-ray examinations.

Owing to the bulk of the stomach-tube and the marked discomfort occasioned by its use, it was impossible to follow the whole cycle of digestion and estimate step by step the exact changes which took place in the stomach after the introduction of a definite stimulus such as various foods. It is true that Hayem² was tireless in the application of the tube and attempted to remove specimens at intervals; but the irregularity of these periods and the inability to obtain subjects who would submit patiently to the repeated introduction of the tube were not the least among its objections. The wonder is that he accomplished as much as he did.

Fundamentally we have accepted Pawlow's statements until most of them have become unquestioned, but there is much to be said against results obtained by his procedures. Bourget,³ the French clinician, is not the only one who protests energetically against the application *sans question* of the results of animal experimentation to man. He says that the physiologist has a tendency to forget that the results which he registered are due to a function perverted or impaired by operative trauma such as fistulas or diverticula. The clinician should take them seriously into consideration, and study them with care, but by no means conclude that they are to be accepted unquestioned. Says Bourget, furthermore, "The physiology of digestion will not make any real progress from a clinical aspect until we have learned to use the sound to determine digestion under the most diversified conditions, but always with the stomach non-traumatized." Much can be said on the basis of this work to support that contention.

We have used a method which one of us⁴ devised and which has been described elsewhere by which it is possible to follow the entire cycle of gastric digestion with practically no discomfort and by which it is possible at any given moment to draw off any or all of the juice secreted in sufficient quantity to perform the necessary chemical examinations. We have already discussed⁵ the inadequacy of the ordinary stomach-tube and substantiated the statements of Harmer and

Dodd⁶ that the stomach-tube does not remove completely the gastric contents. The principle of our tube is entirely that of gravity and the tip is sufficiently heavy to seek the lowest portion of the stomach. Furthermore, it is slotted in such a way as to permit the aspiration of a representative sample of the gastric juice. These perforations represent the maximum bore of the rubber tubing. The instrument is inserted⁷ and left in the stomach for hours until the gastric cycle is completed.

We commenced our studies on healthy medical students and later performed the same test on hospital patients. Our studies represent in all over 100 cases. We used the straight Ewald meal consisting of two pieces of toast and 10 ounces of tea, 2 ounces of which were reserved to wash down the tube, although this was not necessary. The tube was introduced at the close of an Ewald meal and specimens collected every fifteen minutes. (During the first fifteen-minute period, specimens were collected at five-minute intervals.) This collection at fifteen-minute intervals was continued until the close of digestion, which was marked as pointed out elsewhere⁸ by (1) the failure to aspirate any further material; (2) the character of the preceding specimens; (3) the character of the murmur elicited by inflating through the tube and auscultating over the stomach, and (4) lavage, which enabled us to determine the presence of any food residues and their quantity. At first 10 c.c. specimens were obtained, but unless this material was thick, it was found that from 6 to 8 c.c. were sufficient for analysis.

Our method of analysis was that of Bourget's.⁹ The filtered material was collected and 1 c.c. measured off with an Ostwald graduated pipet. Titration was performed with hundredth-normal sodium hydroxid, phenolphthalein being used as an indicator for total acid and dimethylaminoazobenzene and the Sahli iodine method¹⁰ for free acid. The pepsin determinations were made by diluting 1 c.c. of each sample with 9 c.c. of 0.2 per cent. hydrochloric acid in a test-tube and adding Mettler tubes prepared by the Christiansen¹¹ method. The entire series of tubes was placed in the incubator for twelve hours, and the quantity of albumin digested was read off with the aid of a steel scale graduated in millimeters, and a dissecting-microscope.

Medical students absolutely free from any general or gastro-intestinal manifestation were selected as subjects and curves constructed from the data obtained as indicated above. It soon became evident that there was no such thing as a specific isolated curve, deviation from which indicated some pathologic condition. The following phases were considered of importance in the interpretation of the curve:

1. The period of "ascension." This usually occupied the first thirty minutes and indicated the rapidity and intensity of the response to a known stimulus.
2. The character and height of the high point or "acme," whether (a) accelerated or (b) retarded, and whether (a) abrupt or (b) sustained.
3. Period of descent or decline.
4. The character and modification of the food residues.

acidity is evident from the tables given under the hypersecretory type.

In the analysis of the curves many points must be considered. This method not only gives us a complete picture of secretory activity, but it also enables us to follow the evacuation of the material from the stomach and obtain an accurate index of its motor tone. Pathologically we can obtain an exaggeration or diminution of any or all the phases. We see likewise a prolongation of certain phases, particularly the descent out of all proportion to the normal. Further-

Chart 7.—Curves in two cases of chronic gastritis.

more, the character of the specimens is different, and added factors come into play such as mucus, blood, bacteria, food stagnation from previous meals, presence of organic acids, and distortion of the normal total and free acid ratio, each of which can be followed through the separate specimens. Our studies in pathologic cases are necessarily incomplete. To obtain data of value, many cases must be observed and compared. We feel the necessity of extended study along these lines, but wish merely to indicate the results obtained in certain conditions:

1. Two cases of duodenal ulcer: one undoubted, tender point, hunger-pain, persistent occult blood in the movement, the other with the same symptoms, tender point less pronounced, occult blood in the movements and in the duodenal lavage, not found in the stomach contents. The findings were as follows (Chart 6): (a) a rapid rise in half an hour; (b) distinct rather abrupt hyperacidity; (c) rapid decline; (d) rather rapid evacuation of food in one and three-fourths hours; (e) In one case hypersecretion, and (f) no occult blood in the gastric contents. The rapid evacuation is in keeping with the Roentgen findings in 40 per cent. of the cases. These cases are too few to judge the type of curve, but further work should yield interesting findings.

TABLE 4.—ANALYSES IN A CASE OF DUODENAL ULCER

Time	Total Acidity	Free Acidity
5 min.	8.5	4.0
10 min.	21.0	11.0
15 min.	25.0	17.0
1/2 hour	60.0	48.5
3/4 hour	70.0	51.5
1 hour	69.5	51.5
1 1/4 hours	52.0	36.5
1 1/2 hours	23.5	9.0
1 3/4 hours	20.0	7.5

2. Eight cases of gastroptosis which seem to indicate that there is no one type of curve or a single tendency in the elaboration of the secretion. On the hypersecretory, isosecretory and hyposecretory conditions are found engrafted depending on the inherent

tendency, the acquired and associated pathologic states of the mucosa. In the true Stillier type with generalized myasthenia there is a tendency to a late high point and impaired motility. Frequent small meals and tonic measures, including systematic exercises and a sea voyage, resulted in a total disappearance of subjective symptoms and an improvement in the curve as shown in the following case: The first curve showed a total acidity of 38 at one hour, 58 at one and three-fourths hours, a delay in motility to over three hours and hypersecretion. After the sea voyage, hypersecretion was still present, but the curve had practically reached its height in one hour, with a total acidity of 61, and remained sustained until the cessation of digestion in two and one half hours. There was still present, however, a hypersecretion. We believe that the study of the curve in these cases is of the greatest value from a therapeutic point of view, inasmuch as it enables us to appreciate the tendencies at work.

3. Four cases of chronic gastritis, with mucus in all samples, particularly the later ones, figures within normal range but usually low, evacuation normal, curve unbroken, high point late and slow in appearing (Chart 7 and Table 5).

TABLE 5.—ANALYSES IN TWO CASES OF CHRONIC GASTRITIS

CASE 7			CASE 8		
Time	Total Acidity	Free Acidity	Time	Total Acidity	Free Acidity

1 3/4 hours	49.5	40.0	2 1/2 hours	41.5	28.0
2 hours	21.5	...			

In Chart 8 and Table 6 is given the record of a case of hypo-acidity, atony and gastric catarrh showing distinct impairment of motility with very slow and retarded elimination of acid. There was outpouring of little acid and there were no previous food residues.

Chart 8.—Curve in chronic gastritis marked by hypo-acid impairment of motility.

4. Three cases of cholelithiasis with typical in which the attacks were followed patient was operated on for gall-st symptoms. The findings (Charts 7) were: (a) a late hyperacidity; (b) rapid evacuation; (c) rapid decline; (d) chemical evidence of stagnation o

(c) occult blood negative in different gastric samples and in feces. These findings, together with the anamnesis, should enable one to make the diagnosis.

			2 hours	58.0	44.0

Chart 9.—Curve in cholelithiasis.

The tenderness over the gall-bladder region, the rapid evacuation, lack of gastric findings, symptoms, and pain independent of food, together with jaundice after the attack, enabled us to make a diagnosis in one of the cases. Diagnosis was unconfirmed by operation. In another case, old, operation was performed with removal of stones; drainage was employed, but there was recurrence of symptoms (adhesions?). Tetrachlorophthalein test in one case, although not conclusive, seemed to indicate some hepatic insufficiency.

5. Two cases of suspected neoplasm.

CASE 11.—There were pain, some epigastric tenderness four months in duration, loss of appetite and loss of weight, and no palpable tumor, in a woman past 50. This case showed no free acid, a total achylia without presence of pepsin or rennin, no lactic acid, no Oppler-Boas, doubtful occult blood reaction which on subsequent examinations was absent, negative Wolff reaction, albumin was found only in dilutions up to 1:80, and antipyrin reaction of the blood-serum was negative. Roentgen examination was absolutely negative as well as a physical examination, and on the basis of these findings the case was not considered one of malignancy. Pain has subsequently disappeared and the patient has gained 6 pounds by treatment. In this case is shown (Table 8, Chart 11) the rapid evacuation of the stomach in achylia.

Chart 11.—Curve in achylia gastrica

diagnosis, and fluoroscopy by Dr. Pancoast showed an adhesion probably from the old gall-bladder scar to the duodenum.

Subsequent examinations have proved the correctness of the diagnosis, there being a constant reflux of bile in the stomach from adhesions right below the bile-duct.

1 1/2 hours	15.0	.0

6. Two cases of carcinoma.

One (Case 13) operated on for annular carcinoma of the pylorus by gastro-enterostomy showed the very irregular results given in Table 9 probably due to the irregular working of the enterostomy. There was a trace of free acid in the second specimen but it could not be titrated. Throughout all the specimens were found blood, lactic acid and Oppler-Boas bacilli in large numbers as well as a variety of other organisms. Wolff test was positive at a dilution of 1:320.

The other case was a tumor on the lesser curvature, only partially obstructive, producing slight dilatation, and a gradually increasing curve up to 55; occult blood was distinctly positive.

7. A case (Case 14) with ulcer history and hyperacidity, symptoms improved on medical treatment. This case shows a typical hypersecretory curve, with hypersecretion with delayed motility, fat and vegetable residues from a meal ingested twelve hours previous to examination. Occult blood was negative. The case was probably one of healed contracted ulcer.

A study of this case alone is most interesting as it exemplifies what can be demonstrated by the frac-

tional method. The individual in question had an old ulcer history which was cleared up by medical treatment. At times he has outbursts of hyperacidity. The administration of an Ewald meal at 2 o'clock in afternoon six hours after a small breakfast gave the curve demonstrated in Tables 10 and 11 and Chart 12. At five minutes there is a distinct free and combined acid. This is not due to newly formed acid but to the hypersecretion which was present in minor degree. A new

débris and the outpouring of pure acid. Although the stomach was not empty at two and one half hours, it was of interest to see what effect the ingestion of water had in such cases. A new curve commences immediately, having the same general characteristics as the former curve.

Space does not permit us to give examples of the many interesting findings in functional conditions, the significance of which we are still in ignorance. One

point was repeatedly emphasized and that was the fact that the ordinary technic yields little information of value compared to this method. In the first place, it by no means records the high point in every instance, and secondly, it yields absolutely no information as to what has preceded or followed that point; in other words, it represents but one point in the ever-changing phases of the gastric cycle (Chart 13).

CONCLUSION

- 1. By means of the modified gastric tube, we

Chart 13.—Tendencies in curves.

curve commences, rapidly attaining its maximum, indicating excessive irritability of the glandular mechanism, and the specimens obtained, very liquid, show the excessive amount of juice poured out. Toward the end of the first curve every specimen shows large amounts of free fat ingested at the meal six hours before, and microscopic examination shows many vegetable fibers ingested about eighteen hours before. The curve falls, but the specimens preserve their appearance with a lessening amount of food

Chart 14.—Curve in chronic gastritis.

- can study the entire cycle of gastric digestion, recording both the secretory and motor activity.
- 2. We can construct a curve which graphically records the entire course of digestion.
- 3. Information as to the amount of the secretion can be obtained at any point by complete aspiration and by the character of the specimens which are obtained.
- 4. There is no specific curve for the normal person, but three types of curve can be found depending on

the rapidity of reaction to a given stimulus, the height of the curve and the descent of the curve.

5. These types may be termed, respectively, the hypersecretory, hyposecretory and isosecretory types, depending on their respective reaction to such stimuli.

6. Figures approximating those commonly regarded as hyperacidity are to be found in some period of the curve in a large number of normal persons.

7. A "continued" secretion is described in normal persons which is intimately linked with alimentary and chronic hypersecretion, but can be distinguished from them.

8. The value of this method in various pathologic states is emphasized and a limited number of cases are reported together with their findings.

9. The technic commonly employed for estimating gastric function is entirely inadequate, inasmuch as it indicates but one phase in a constantly changing cycle, and that phase is by no means always the high point in the digestive curve.

10. We would insist on the great advantages of this method which, correlated with the various tests performed on different samples as well as the special tests described elsewhere, enables us to make a more perfect study of the digestive cycle than has hitherto been possible.

We wish to thank Drs. McCrae, Hare and Cohen of the medical staff of the Jefferson Hospital, as well as Drs. Livingood and Wayland, the resident physicians, for their interest and cooperation in this work.

EXPERIMENTAL RESEARCHES IN METHYL ALCOHOL INHALATION *

H. H. TYSON, M.D.

AND

M. J. SCHOENBERG, M.D.

NEW YORK

Notwithstanding the earnest efforts of the ophthalmologists and the various committees for the prevention of blindness, to disseminate the knowledge of the poisonous qualities and effects of methyl alcohol, it is still a lamentable fact that many members of the medical and legal professions and the vast majority of the laymen, especially the workers using it, are either ignorant of or do not acknowledge the truth. The effect on the eyes and general health from drinking wood alcohol has been proved experimentally in animals, and has been corroborated in clinical practice; but the effect from its inhalation alone on the eyes has never heretofore been demonstrated experimentally.

Although many clinical data have been collated tending to show an effect similar to the one obtained from its imbibition, many doubt and some dispute its power to affect the human organism deleteriously through inhalation alone. The wish to prove this fact, coupled with a desire in the interest of humanity to lessen the number of the blind and to conserve life, by advocating proper preventive or precautionary measures for

workers using it, induced us to undertake these experiments.

Before giving them in detail, it may be of interest briefly to refer to the importance of the subject to the body politic.

We have found that there have been about one hundred cases of amblyopia and death from inhalation of wood alcohol recorded in the literature to 1912, and we are of the opinion that this constitutes a very small percentage of the total number of cases which have actually occurred, as a great many either have not been recorded, or have gone unrecognized. Of those that have appeared in the literature, the question whether inhalation alone produced the condition, has usually arisen. In conducting our investigations, we have endeavored to exclude all possibility of the entrance of the wood alcohol into the system except by inhalation, and we feel sure that we have succeeded in producing amblyopia and death in that manner, as we contemplated at the beginning of these researches.

In 1880 about 400,000 gallons of wood alcohol were manufactured, while in 1910 the amount had increased to over 8,000,000 gallons; consequently it appears that the industry has become firmly established. That being true, it is for the chemists and medical profession so to arrange for its use or composition that, while it may serve its purpose in the arts and industries, it shall not levy too heavy a toll on the artisans, and indirectly on the state by causing blindness or death. Its use is extensive, about 2,000,000 people working in trades are using it in the United States alone, and as the foregoing figures indicate, its use is increasing annually.

According to the 1904 United States Census, the following industries and trades were using wood alcohol.

Painters, glaziers and varnishers...	278,000 workers
Launderers	386,000 workers
Boot and shoemakers.....	208,000 workers
Barbers	131,116 workers
Printers and lithographers.....	155,000 workers
Woodworkers—piano, furniture, etc.	112,000 workers

About 500,000 workers divided among dye-work operators, brass-workers, cabinet-makers, gold and silver workers, harness-makers, hat-makers, leather-workers and tanners, metal-workers, photographers, book-binders, chemists, etc.

The subject is one of increasing importance on account of the new employers' liability law in New York and other states. At present it is not even mentioned specifically as a hazard, but when the importance of the effect of its inhalation is realized, cognizance of this omission must surely follow.

The manufacturers assert that even admitting that commercial wood alcohol is poisonous, the refined product known as Columbian Spirits is not. We have proved conclusively that the refined spirit is quite as dangerous as the unrefined; and indirectly more likely to destroy vision and life on account of the absence of the disagreeable odor to warn one of its presence.

Our original intention was to note the effect of methyl alcohol inhalation in chronic cases, that is, in those which had been exposed to its influence in small quantities over a long period. But the time allowed in which to prepare our paper for the meeting was most inadequate to conduct our investigations along these lines, so we were obliged to confine our attention principally to the more acute phases of the matter under consideration.

* Read before the Section on Ophthalmology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

* Because of lack of space this article is abbreviated in THE JOURNAL by the omission of several experiments. The complete article appears in the Transactions of the Section and in the authors' reprints.

The apparatus used in our investigations consisted of a wooden box which was 32 cm. wide, 47 cm. long and 63 cm. deep (high) with an opening on each end about 1 cm. in diameter. In one end a mica valve was very delicately adjusted, allowing air to pass out. At the other end was an attachment for tubing which could be connected with an air-tank, or copper coil, and which acted as an inlet for fresh air. The top, in which were two square glass windows, could be fastened down by eight thumb-screws. The temperature of the air in the box for the experiments averaged about 68 F., while the hygrometric readings indicated an average of about 60 per cent., thus to a certain extent constituting conditions similar to those in which some of the workers with methyl alcohol use it, for example, varnishers in beer-vats, etc.

The wood alcohol used in the experiments consisted of both the commercial and the Columbian Spirits, and they were obtained from Eimer and Amend, chemists of New York City.

RESEARCHES IN METHYL ALCOHOL INHALATION IN ANIMALS

EXPERIMENT 1.—Acute poisoning in dog. Dec. 3, 1913: A dog, male, weight 4 kg., 700 gm. (about 10 pounds), fed one hour before experiment. At 4:15 p. m. was placed in the box with 2 ounces of wood alcohol on a sponge; inlet and outlet of box open for fifteen minutes during which time dog jumped and barked, then openings were closed. Room temperature 64 F. Interior of box temperature 70 F. Dog at 4:50 p. m. was lying quietly on his side. At 5:30 p. m. box was opened, dog appeared intoxicated; fell on attempt to walk. Moved his head from side to side.

December 5: Breakfast: meat and bread, at 11:30 a. m. At 4:30 p. m. dog was placed in box with 4 ounces wood alcohol on two sponges and box closed. At 4:40 p. m. dog was lying down, abdomen up, breathing heavily. At 4:50 p. m. dog's mouth was slightly open, tongue projecting and body in a position of opisthotonos, abdomen upward, animal moving fore feet feebly. At 5:05 p. m. dog unconscious, respiration 50 per minute. At 5:25 p. m. box opened; dog taken out apparently dying.

December 8: Dog recovered in thirty-six hours, and whereas on the 5th he was dull, he now appeared lively and well. Was placed in box with 5 ounces wood alcohol; box closed at 5:10 p. m. At 5:50 p. m. dog was taken out intoxicated, breathing heavily.

December 9: Dog appeared lively and well, and remained so.

December 30: Dog was placed in box with 5 ounces wood alcohol at 1:50 p. m. At 5:10 p. m. was observed lying on right side with tongue protruding and twitching of fore legs; was taken out of box. Examination: Temperature 90 F.; eye tension, Schiötz tonometer 26 mm. Hg, although its palpation seemed much lower, tonometer reading possibly little higher due to pressure of eyelids and to contraction of lid muscles; respiration 29 per minute, labored; blood-serum not alkaline to phenolphthalein; slightly alkaline to litmus; aqueous humor not alkaline to phenolphthalein; slightly alkaline to litmus; twitching of eyelids; cornea only slightly hazy; pupils 3 mm., no light reaction; fundus of eye, optic disk congested with edema; veins dark and dilated, arteries small.

December 31: Dog apparently dying; respiration 10.

Jan. 2, 1914: Dog found dead in morning.

Remarks.—This dog had four exposures to wood alcohol inhalation, spread over a period of one month. He died after the fourth exposure. It is interesting to note the continuous movements of the head from

side to side, which we venture to attribute to an irritation of the semicircular canals of the internal ear.

EXPERIMENT 5.—Effect of methyl alcohol inhalations, with and without ventilation. Dec. 18, 1913, at 4:05 p. m., a dog, weight 3,980 gm. (about 9 pounds), lively, eyes normal, was placed in box with inlet and outlet working. Through inlet air is pumped in at rate of 28 pumpings per minute under 2 pounds pressure. The air passes through a Woulfe bottle, which contains 3 ounces of Columbian Spirits. The vapor is thus forced through a copper spiral or coil placed in a pail of water, under which is a Bunsen burner to heat water and coil. After passing through coil it enters box warmed. At 5:05 p. m. dog was taken out of box lively and apparently unaffected.

December 20: Dog placed in box for twelve minutes. Experiment as before, allowing vapor to pass directly from Woulfe bottle into box without being warmed. Air-pressure $2\frac{1}{2}$ pounds—26 pumpings per minute. At 5 p. m. hygrometer in box, 40. After remaining in box $5\frac{3}{4}$ hours dog was lively, showing no apparent effect of vapor.

December 22: Condition as before. Dog in box from 12 m. to 3:30 p. m. having had 5 ounces of Columbian Spirits pumped in with no apparent effect.

December 27: Placed in box at 11:55 a. m. with $2\frac{1}{2}$ ounces wood alcohol pumped in under $2\frac{1}{2}$ pounds pressure; taken out at 5 p. m. lively; no apparent effect.

December 29: Through error of attendant, dog placed in box with 5 ounces wood alcohol without free ventilation. Examination at 4 p. m. found dog lying on right side, with tongue protruding, frothing at mouth, hair moist; was taken out of box. Respirations 20 per minute; deep reflexes absent; unable to stand; comatose.

December 30: Dog still comatose, lying on right side. Respiration shallow, irregular 50 per minute. Temperature 90. Eyes: tension from 6 to 8 mm., both corneae only faintly hazy; sensibility slightly diminished; pupils 3 mm. light reaction; aqueous humor not alkaline to phenolphthalein, neutral to litmus; fundus, optic disks red and edematous; arteries small, veins dark red and dilated. Blood-serum not alkaline to phenolphthalein, slightly alkaline to litmus.

December 31: Dog found dead in morning by attendant.

Remarks.—This experiment is a striking illustration showing the diminished resistance to the inhalation of Columbian Spirits when a very free ventilation was abolished. Moreover, we believe that the repeated exposures to the inhalation of Columbian Spirits (even with free ventilation) did have some effect on the dog, and that the last exposure had a quick fatal effect on account of the previous exposures.

EXPERIMENT 6.—Acute poisoning in rabbit. Dec. 13, 1913, a rabbit, weight 1,600 gm. ($3\frac{1}{2}$ pounds), was placed under a large bell jar with 5 ounces Columbian Spirits, and three minutes later was rubbing its nose. Respirations 50 per minute. Every seven or eight respirations spasmodic contraction of diaphragm resembling hiccup. At 4:55 p. m. respirations 32 per minute, with occasional convulsive rapid shortening of the body. Hygrometer 80. Taken from under jar at 5:05 p. m.

December 20: At 4:45 p. m. animal was placed under large jar with 5 ounces Columbian Spirits. At 5:45 p. m. respirations 40 per minute; hygrometer 70; taken out from under jar, not much effect shown.

December 23: At 3:40 p. m. animal under jar with 3 ounces Columbian Spirits. At 4:45 p. m. respirations 38; hygrometer 70; temperature in jar 68. Taken out in good condition.

December 27: At 11:55 a. m. animal under jar with 5 ounces Columbian Spirits. At 12:55 p. m. hygrometer 55; at 1:35 p. m. respirations 57. At 2:30 p. m. respirations 50. At 4 p. m. animal lying on side quietly; breathes regularly and deeply, 22 per minute. At 4:40 p. m. respirations 16;

at 4:45 p. m. respirations 4. Taken out from under jar; cornea hazy; no lid reflex; no light reflex; nose and ears cold. Temperature by rectum 90 F.

December 29: Found dead in morning. Eyes preserved in formaldehyd solution.

Remarks.—The rabbit appeared to be more resistant to the Columbian Spirits than the dog was. Coma and death came only after the fourth exposure, although relatively larger amounts of Columbian Spirits were used. The same spasmodic contractions of the body and diaphragm were noticed as in former experiments.

EXPERIMENT 8.—Acute poisoning in dog. Jan. 3, 1914, a dog, male, weight $5\frac{1}{2}$ kg. (12 pounds), was placed in box at 12:55 p. m., inlet and outlet closed; 5 ounces methyl alcohol commercial. At 1:50 p. m. animal staggered about, frothing at mouth, and at 2:50 p. m. was unable to stand; at 4:10 p. m. lying on right side; respirations 25, deep and labored. Dyspnea at 4:55 p. m.; respirations 24; pulse 150; eyes, cornea clear, sensibility diminished; pupils 2 mm. contracted; no light reaction; fundus, optic disks hyperemic, with edema; arteries small, veins dark, slightly dilated. Tension, left 18.5. Aqueous humor slightly alkaline to litmus, not alkaline to phenolphthalein. Respirations short; inspiration prolonged, expiration about as one to four. Hygrometer 55; temperature in box 66 F. Dog remained in comatose condition from January 3 to 5; was found dead the morning of the 5th, lying in same position as when examined on January 3 and 4.

Remarks.—Death was produced by one prolonged exposure (four hours). The intra-ocular pressure was not low January 3, soon after the exposure, and the animal lived more than twenty-four hours, a fact which confirms previous conclusions, namely, that when the tonometer shows a normal intra-ocular pressure, the animal, though in an apparently dying condition, will live at least twenty-four hours or more, and an intra-ocular pressure below 5 mm. Hg is a sign that death will follow within twenty-four hours.

EXPERIMENT 10.—Changes in the electroconductivity in the blood of a dog produced by methyl alcohol inhalation.

Jan. 17, 1914: Dog, weight 5 kg., 570 gm. ($11\frac{3}{4}$ pounds). Under ether anesthetization 15 c.c. of blood were obtained to which was added 5 c.c. of a 1 per cent. aqueous solution of ammonium oxalate. The electroconductivity was measured by Edelman's Universal Widerstands Brücke; see technic.¹

(1) Sample of dog's blood mixed with ammonium oxalate 3 to 1; (2) bridge reading, 39.4; (3) resistance out, 100; (4) temperature 9 C. (48.2 F.) = 65.017 ohms resistance at 9 C.; = 54.615 ohms resistance at 17 C. (62.6 F.).

January 20: Dog kept in box three hours with fumes from 5 ounces wood alcohol. Respirations 42, labored; at end of time lies on right side unconscious. Temperature below 94 F. Eyes: cornea slightly hazy; corneal and pupillary reflex abolished; fundus, edema of disks with dark veins; arteries small.

Blood was obtained from which the bridge reading was 34; resistance out 100; temperature 17 C. = 51.515 ohms resistance at 17 C. Dog killed with chloroform; eyes and optic nerves were enucleated and preserved in formaldehyd solution.

Post-mortem Examination.—Pericardium contained large amount of colorless transparent fluid which spurted out as if under pressure when it was incised; macroscopically heart appeared normal; stomach and intestines were dilated; interior of stomach and pylorus very markedly congested; cupful of frothy mucus found in stomach; spleen very dark indigo blue.

Remarks.—This experiment showed that the electroconductivity of the serum was increased after the inhalation of wood alcohol. The difference of 3.1 ohms resistance obtained in testing the electroconductivity of the blood showed a change which might result from the breaking up of the corpuscles, from an increase in H-ion content, or from any increase in the inorganic salts. An increase in the H-ion content will produce an increase in the acidity of the blood and also conduces to an edema of the tissues. As we find evidence in the blood of acidosis, and a tendency to edema of the ocular tissues, we think that the increase of its electroconductivity, following methyl alcohol poisoning, is due to an increase in the H-ion content of the blood.

EXPERIMENT 11.—Acute poisoning by inhalation in a monkey. Jan. 22, 1914: Female monkey in good health, weight 4 kg. (8.8 pounds), 1 per cent. solution of atropin instilled into eyes. Apparently did not like the bitter taste, as it evidently passed through nasal duct into mouth. It kept expectorating and washing out its mouth; gagged several times as if nauseated. Eyes: pupils dilated quickly and at maximum; fundi, periphery very dark, uniformly pigmented, no abnormalities; disks appear normal and are oval, long diameter vertical.

January 29: Temperature 102 F. per rectum. Monkey placed in box with 3 ounces methyl alcohol spread over sides of box. At 4:25 p. m. air pumped in under $2\frac{1}{2}$ pounds pressure thirty times per minute. Monkey sat in one corner opposite air inlet and no apparent intoxicating effect was produced whatever; at 5:10 p. m., wood alcohol, 1 ounce additional introduced into box; at 5:25 p. m., taken out; monkey acts normally.

February 3: General condition good. At 5 p. m., in box with 3 ounces wood alcohol; same condition; temperature 100.6; at 5:50 p. m., taken out, temperature 100.2 F.

February 4: At 1:35 p. m., in box; temperature 101.4; out at 3:15 p. m., temperature 102; staggering gait, acted dazed and slightly intoxicated. Three ounces wood alcohol used, box with open ends.

February 5: At 2:55 p. m., in box; temperature 102; out at 4 p. m., temperature 100.6. Three ounces wood alcohol used. At 3:35 p. m., animal winking; slight watery discharge from nose.

February 6: At 2:45 p. m., in box; temperature 101.6; out at 3:45 p. m., temperature 101.6.

February 7: At 3:05 p. m., in box; temperature 102; out at 4:30 p. m., temperature 102; 3 ounces wood alcohol placed on cotton, high up, near top of box; monkey not affected apparently by vapor.

February 9: At 3:15 p. m., in box; temperature 102; out at 4:15 p. m., temperature 102; no effect. Wood alcohol 3 ounces.

February 10: In box at 2:55 p. m., temperature 102; out at 4:40 p. m., temperature 100; pulse 160; optic disks hyperemic as compared with first examination; veins dark; pupils dilated, sluggish to light, acts sleepy. Wood alcohol 3 ounces.

February 11: At 3 p. m., in box; wood alcohol 3 ounces; temperature 102; out at 4 p. m., temperature 101.6; staggering gait, weak hind legs; eyes red and watery; drowsy, falls forward in attempting to walk.

February 12: At 10:20 a. m., in box; temperature 101; out at 11 a. m., temperature 99. Wood alcohol 3 ounces.

February 12: At 4:10 p. m., in box; temperature 103; out at 4:20 p. m., temperature 102; vomited, much affected, scarcely able to walk; hygrometer 65.

February 13: At 9:45 a. m., in box with 5 ounces wood alcohol; temperature 100.4; out at 10:45 a. m., temperature 100; drowsy; much affected; very weak, nausea, vomiting. At 4 p. m., temperature 98.8; acts ill, face, gray pallor, refused to eat chocolate, of which was very fond. Keeps quiet; eyes red, pupils dilated, surface of body cold;

1. Centralbl. f. Electric., 1887, p. 115.

wrapped up in covers, sits with head down between fore legs; placed in room by warm radiator.

February 14: At 8 a. m. found dead; body warm, apparently just died. No evidence of painful death. Head removed, eyes enucleated. Necropsy at 5 p. m. macroscopically. Pancreas and adrenals normal; kidneys slightly congested; liver slightly darker than normal, uniform color, no apparent degeneration; uterus and ovaries normal. Heart, pericardium slightly congested; empty; no blood clots nor fluid. Lungs normal, crepitate and float; spleen small, indigo color characteristic of wood alcohol cases; preserved in formaldehyd solution. Large intestines very much inflated containing also mass of feces and a thrombus in the intestinal mucosa. Small intestines not much bloated; empty of fecal matter but in upper part sections or links bloated with occasional dilatation of vessels; stomach contains yellowish-green tenacious semifluid homogenous mass of mucus with small pin-point hemorrhages along vessels, with dilated veins; dura markedly and pia mater slightly congested; spinal cord appeared normal.

Remarks.—The shortness of time of inhalation with free ventilation, and the small amount of wood alcohol used, explain the lack of effect on the monkey during the first two exposures. But this lack of effect was only apparent, as the animal began to show weakness of hind legs, loss of appetite, diarrhea and vomiting after the subsequent exposures. That death followed the last exposure, in which 5 instead of 3 ounces of wood alcohol were used, is very significant. We are convinced that a latent debilitated condition which was not recognized, existed, and the last dose acted fatally as an overdose. The pin-point hemorrhages on the gastric mucosa is one of the characteristics of wood alcohol poisoning.

EXPERIMENT 13.—Acute poisoning in dog by inhalation of Columbian spirits, with marked ocular hypotension. Feb. 28, 1914: Dog, weight 5 kg., 900 gm., male. At 8:35 a. m., in box with 10 ounces Columbian Spirits; temperature 102.6; out at 11:15 a. m. In box at 12 m., out at 3:20 p. m., temperature 96. In box six hours; during first hour frothed at mouth; required about one hour to be intoxicated, then comatose; at 4 p. m., respirations 28; auscultation showed short inspiration with long expiration; pulse 88 by stethoscope; temperature below 93. Some fibrillary contractions of muscles of face, mouth, neck, nose and tongue. Intra-ocular pressure less than 3.5 mm. Hg with Schiötz tonometer. Not much bleeding during enucleation, but more than when commercial wood alcohol was used; bleeding stopped readily (viscosity increased, coagulation time reduced). Died one hour later as expected, using the marked hypotension as an indication of the proximity of death. The examination of the ocular fluids showed a marked reduction in alkalinity.

EXPERIMENT 14.—Changes in chemical reaction of serum and aqueous humor. March 3, 1914: Female dog, weight 5 kg., 800 gm. Aqueous humor withdrawn by aspiration under cocain anesthesia. Four-tenths c.c. obtained from left eye. Alkaline: $48 - 47.90 = 0.10$; acid: $28.10 - 28 = 0.10$; result, neutral to phenolphthalein.

March 5, 1914, 10 a. m.: In box; temperature 101; out at 12:30 p. m. In box 12:45 p. m., with 5 ounces Columbian Spirits; out at 4 p. m., temperature 95. Eyes: pupils 3 mm.; 5 p. m.—O. D., tonometer=3.5; O. S.=3.5; (blood examination morning and evening). Died next day as indicated by very low hypotension. Right eye, aqueous 0.4 c.c. Titrated with phenolphthalein as an indicator. Alkaline: $32.4 - 29.5 = 2.90$; Acid: $31.10 - 29.95 = 1.15$; Alkaline: $2.90 - 1.15$ acid=1.75 alkaline=4 c.c.; 4.48 tenth normal sulphuric acid to 1 c.c. Normal blood-serum 0.1 acid=1 c.c. Blood normal 0.5 c.c. Twenty c.c. water. Alkaline:

$33 - 32 = 1.00$; acid: $31.95 - 31 = .95$; alkaline $1.00 - \text{acid } 0.95 = .05$ alkaline. One c.c.=0.1 blood tenth normal sulphuric acid to phenolphthalein. Serum taken in morning.

Blood after exposure to Columbian Spirits vapor: Alkaline: $23 - 22 = 1.00$; acid $32.85 - 32.00 = .85$; alkaline $1.00 - \text{acid } .85 = .15$ alkaline. One c.c. blood-serum=0.15 tenth normal sulphuric acid.

Remarks.—As we see, the serum of the dog before inhalation was 0.10 tenth normal sulphuric acid; aqueous humor was neutral; serum after inhalation was 0.15 tenth normal sulphuric acid; aqueous after inhalation was 4.48 tenth normal sulphuric acid. It is very significant that the aqueous shows more acidity than the blood.

EXPERIMENT 15.—Control. Feb. 3, 1914: Male dog, weight 3 kg., 300 gm., was placed in box as control with inlet and outlet open (no methyl alcohol vapor added). Animal was kept in box four hours. No apparent effect; was active and lively when taken out.

February 7, 9:55 a. m.: In box, temperature 103.4; out at 1:15 p. m., temperature 102.6; box closed tight, no ventilation; when taken out box contained bad (close) odor. Dog showed no bad effect.

EXPERIMENT 16.—Acute poisoning with Columbian Spirits showing acidity of aqueous humor and increased viscosity of blood. March 7, 1914: Male dog, weight 6 kg. (about 12 pounds), in box with 10 ounces Columbian Spirits. At 9:30 a. m., in box; temperature of dog 104; out at 1:45 p. m., temperature 97. At 2:45 p. m., in box; temperature 95; out at 4:15 p. m., temperature 94. Pupil contracted to 2 mm.; no reaction to light; dog comatose; aqueous withdrawn with needle, 0.7 c.c. Alkaline: $24.00 - 23.00 = 1$; acid $34.85 - 34.00 = 0.85$; alkaline, $1.00 - \text{acid } .85 = .15$; 0.7 c.c.=0.15. One c.c.=0.21 tenth normal sulphuric acid to phenolphthalein as indicator.

Remarks.—As normal aqueous showed neutral reaction, this test is interesting on account of acid reaction as determined.

March 9, 9:30 a. m.: Temperature 96.4; animal comatose; pulse 20; respiration 6. Pupils 2 mm., contracted; no light reaction. Corneal reflex abolished, anesthetic; O. D., fundus hyperemic and edema of optic disk; arteries small, veins not altered in size. At 4:30 p. m., temperature 95 F.; respiration 6; pulse 20. O. D. enucleated and placed in 5 per cent. formaldehyd solution for microscopic examination, no bleeding during operation until optic nerve was severed, then slight hemorrhage occurred, about 1 dram dark viscous blood which coagulated readily. Surface of body cold; respirations slow and deep; eyes closed; tongue dry and protruding; animal comatose; pupil, no light reaction—tonometer 3 by palpation, all reflexes abolished; animal in moribund condition.

March 10: Found dead at 8 a. m. Necropsy: Brain reddish; meninges and substance of brain (white and gray matter) congested. Lungs, pleural cavity contains about 2 c.c. sanguineous fluid, surface of left lung shows numerous small hemorrhages; lung substance slightly edematous and floats on the surface of water. Trachea, normal, not congested. Heart, full of dark blood-clots. Spleen, dark indigo-blue throughout. Liver and bile both darker than normal. Kidneys, bluish-red, very dark, much congested. Adrenals and pancreas darker than normal. Stomach, empty; numerous small punctate dark purple hemorrhages along lesser curvature. Intestines, bloated and empty, purplish-red, similar to lining of stomach.

Remarks.—The symptoms, chemical reactions of the aqueous and post-mortem findings we consider typical of acute poisoning with methyl alcohol.

3. Blood-serum 1 c.c.=0.05 increased acid in case after Columbian Spirits.

2. When tension is less than 5, dog usually dies within 24 hours.

BLOOD-COUNT IN DOG WITH ACUTE POISONING BY INHALATION OF METHYL ALCOHOL

Before inhalation:

○ Erythrocytes	5,700,000
Leukocytes	11,800
Hemoglobin	90 per cent.
Polymorphonuclears	79 per cent.
Lymphocytes	21 per cent.

After inhalation (2½ hours):

Erythrocytes	7,800,000
Leukocytes	28,600
Hemoglobin	100 per cent.
Polymorphonuclears	99 per cent.
Lymphocytes	1 per cent.

Remarks.—Besides the increase in the erythrocytes, leukocytes, hemoglobin and polymorphonuclears, the very marked decrease in the lymphocytes is of decided interest.

MICROSCOPIC FINDINGS IN EYES OF DOG WITH SUB-ACUTE POISONING

HEMATOXYLIN EOSIN AND VAN GIESON

1. Choroid gives the impression of hyperemia.
2. Tapetum normal. Retina: rods and cones and the external nuclear layer normal.
3. Outer reticular layer slightly edematous.
4. Inner nuclear layer, normal.
5. Inner reticular layer, slight edema.
6. Ganglion cells swollen and surrounded by clear areas, the nuclei being displaced far toward the periphery.
7. Inner layers of the retina show some edema.

WEIGERT

1. The medullary sheath of the optic nerve takes Weigert's stain rather weakly.
2. A few vacuoles show at the ends of the rods and cones. The Marchi and Nissl specimens have not been finished, the report of these will be published later.

We consider methyl alcohol to be a true hemato-toxic. It has a decided effect on all tissues, producing degenerations, and under certain conditions amblyopia or death. In the eye it produces first a toxic edema of the tissues, which, with the increased viscosity of the blood, interferes with its free circulation. The tissues, being deprived of their nutrition and oxygen, succumb to the effect of the toxin, and degeneration of the ganglion cells and nerve fibers ensues. Acidosis occurs as indicated by the results of the titration of the aqueous and serum, and by the determination of the electroconductivity of the blood.

The tension of the eye in methyl alcohol coma may be a guide as to the immediate outcome of the case, and with more study a scale might be formulated giving exact points at which, as regards life, one could prognosticate complete recovery or death.

Hypotension of 5 mm. Hg or less indicates death within twenty-four hours, while with tension over 5 the animal lived longer; and in these cases a question arises whether or not, if proper treatment was instituted early, the animal would recover.

SUMMARY

Effects of experiments with methyl alcohol inhalation were the following:

1. In nose and mouth copious discharge and frothing.
2. Temperature: marked fall, varying from 1 to 10 degrees according to amount used, method and time of exposure to vapor.
3. Respiration: rate increased, then decreased below normal, being very low just prior to death and ceasing before heart.

4. Blood: increase in electroconductivity due to an increase in H-ion content. Increased acidity, with phenolphthalein as an indicator. Coagulation time reduced, specific gravity increased. Viscosity increased. Erythrocytes, leukocytes, hemoglobin and polymorphonuclears increased and lymphocytes decreased.

5. Necropsy findings: Stomach: empty, mucous membrane congested, punctate hemorrhages. Trachea: pale. Lungs: few minute hemorrhages on surface. Heart: muscle dark, in some cases cavities, empty. Liver: dark. Kidneys: dark purple, congested. Adrenals: hemorrhage in one case. Spleen: dark indigo-blue. Intestines: bloated, small punctate hemorrhages. Brain: marked congestion of the meninges.

Effects on the eyes were: Slight irritation producing blinking, slight haziness of cornea and no inflammation of conjunctiva. Corneal reflex retained in some animals after others had disappeared. Fundus: Hyperemia and edema of the disks, with dilated, dark veins and arteries. Pupil: Moderate contraction in coma, with loss of light reaction. Tension varies with intensity of toxemia, in mild recoverable cases being normal, and in profound coma showing marked hypotension, which when less than 5 mm. Hg by tonometer, indicated a rapid and fatal termination within about twenty-four hours.

Aqueous by titration (with phenolphthalein as an indicator) showed an acid reaction.

In one dog (Experiment 9) blindness was noticed, judging from the animal's collision with objects when attempting to walk, as he could not see to get around them.

Microscopic findings indicate an edema of the tissues with very early signs of beginning degeneration of the ganglion-cell layer of the retina.

In reviewing the results of these experiments, attention is directed to the similarity with those obtained through experimental researches and clinical observations, in the internal administration of methyl alcohol; thus demonstrating its fatal and profound toxicity irrespective of the method of its entrance into the animal organism.

The contentions of the manufacturers that the refined methyl spirits are absolutely harmless are untenable and may cause many sad results among workmen by rendering them careless in taking proper precautionary measures while working with it. Many consider its inhalation harmless under ordinary ventilation. We take exception to that supposition. Most of our inhalation clinical cases result from its toxicity under what are considered by the workmen ordinary conditions. While ventilation will diminish the intensity of the toxicity, the inhalation will not be rendered absolutely harmless thereby. Not ordinary ventilation, but the very best obtainable is required for workers using wood alcohol. At least three times the ordinary air-space allotted per person should be allowed to each workman using it. Placards warning of the poisonous properties of wood alcohol should be posted in conspicuous places about premises where it is used, and hours of labor should be so arranged as to allow for exercise in the open air at frequent intervals. In our subacute cases while the exposure to the vapor for an hour or two daily had not much apparent untoward effect at the time, it certainly did have an effect which manifested itself later by subsequent weakness, trembling and unsteady gait in the intervals between expos-

ures. We are inclined to agree with M. L. Poincaré,⁴ who found, after exposing animals to small quantities of vapor of methyl alcohol over a period of from eight to sixteen months, that considerable fatty degeneration of tissues occurred, especially in the liver, heart, muscle, epithelial cells of the uriniferous tubules, some cells of the lungs, and with congestion and slight inflammation of the meninges, and of some nerve centers. He concluded that the vapor of methyl alcohol in small quantities was dangerous.

Physicians often fail to recognize industrial and occupational diseases because of the fact that they are often masked under the form of chronic disorders, which show themselves in obscure diseases of the digestive tract and nervous system, and are attributed by patients to other causes. A number of cases of methyl alcohol poisoning, to our knowledge, have occurred in which the causes of death were given as pneumonia, meningitis, heart-disease, etc. Many of the milder cases have been treated for chronic gastritis, hepatitis, etc. It is not surprising that these unfortunate persons travel from one physician to another searching for relief, when we consider the unfortunate but sad truth that many physicians fail to grasp the true etiology of the cases.

That a difference in susceptibility to methyl alcohol exists in animals and man cannot be denied, and this can be partly explained by the rate of oxidation which takes place in the animal or person. Those in which it is rapidly oxidized experience the least effect, while those with slow oxidation feel the greater toxic effect. Harnack⁵ concluded that methyl alcohol in slow oxidation formed formic acid, while in rapid oxidation carbon dioxid and water were formed. Hence when it is rapidly oxidized, it is comparatively (?) harmless, while in slow oxidation, which usually occurs in man, it is exceedingly toxic, as the action of the formic acid thus produced in the animal organism was much stronger than that of the pure formic acid introduced into the body, as in the latter case the organism attempts to convert it with bases and thus gives rise to formates.

In 1869 Richardson⁶ suggested that methyl alcohol be inhaled as an anesthetic. He stated that 2 ounces required one hour to produce anesthesia, and pointed out that reflex irritability was not abolished by small doses, that the temperature of the body was reduced 3 degrees and that the danger from its use was practically nil; but when inhalation was forced, death was produced by simultaneous cessation of respiration and circulation. We do not know the time required for him to gain the knowledge contained in the last sentence, but trust that it was during his very early use of methyl alcohol.

It is a well-recognized fact in pharmacology that poisons which affect the highly differentiated nerve-structures very powerfully are proportionately more dangerous the more highly developed the nervous system of the animal is, hence it would be expected that man would be relatively more susceptible to such a poison as methyl alcohol than would the dog or rabbit.

The results of the experiments with the titration method agree with the conclusions formed by Greg-

nolo,⁷ who determined, after the ingestion of methyl alcohol, that there was an increase in the concentration of H-ions in the aqueous and serum, and who stated that these changes go parallel with the morphologic changes in the tissues of the eye. His experiments show, as do ours, that the substances produced in the body by poisoning with methyl alcohol are extremely diffusible and penetrate the eye readily. Our microscopic specimens having been obtained from acute cases show only the stage of edema with an indication in the ganglion cells of one of the first signs of degeneration, the location of the nucleus being far toward the periphery of the cell and most of the cells showing this change. As to the fate of methyl alcohol in the human body, Pohl⁸ found that it underwent the same change as in that of the lower animals, its administration leading to the appearance of formic acid which is slowly excreted in the urine.

R. Hunt⁹ states that experiments on the physiologic action of methyl alcohol show conclusively that, however pure the preparation may be, it is totally unfit for use as a substitute for grain alcohol in any preparation which is to be taken internally or used externally, or, we add, which may be inhaled in a concentrated form.

USE OF SPECIALLY DENATURED ALCOHOL RECOMMENDED

Only those who have had experience realize the power and intensity of the opposition encountered in endeavoring to obtain proper protective legislation for the regulation of the sale and use of methyl alcohol. When it is possible for one or two members of a legislative body working in the interests of methyl alcohol manufacturers to be able to thwart the wishes of the vast majority of the inhabitants of a great state for a just protective law regulating the safe and proper labeling of methyl alcohol, it is a most unjust and deplorable state of affairs. If the law regulating the sale of specially denatured alcohol could be amended so that manufacturers might be permitted to sell this alcohol to the individual trades using it in the various industries, which would allow them to prepare their own varnishes, etc., obtaining the consistency desired, one of the objections to its present use would be overcome. The variety of denatured alcohol which the law now compels them to use contains a denaturing agent which renders the varnish of soft consistency, and after having dried it scratches very easily, leaving a white mark. If the trades could obtain the denatured alcohol without the objectionable denaturing agent (benzin, pyradin, etc.) it would in a short time supplant the methyl alcohol to a great extent, as it is only one-tenth as dangerous, and if it is used in an exceedingly well-ventilated space, the fatal results due to the toxicity of methyl alcohol would be reduced to a minimum.

The laws relating to methyl alcohol should be enforced with a jail sentence as a penalty attached. Until the gravity of the situation is realized by our law-makers and the judges in our courts, a certain number of manufacturers who value human life cheaply will continue to be a menace to society by disregarding the law and thus causing blindness and death.

TREATMENT

While heretofore treatment, except in a very small proportion of the cases of methyl alcohol poisoning with amblyopia, has been considered rather hopeless, the few patients who have improved or recovered, should stimulate us in our efforts to go forward with renewed vigor in search of a plan of medication which shall yield better results. A plan of treatment based on our findings might be summed up in two words, eliminate and stimulate. Eliminators of all varieties should be used, namely, emetics, hydragogue cathartics, diuretics and diaphoretics, calomel, jalap, pilocarpin hypodermatically, hot saline baths or packs, saline infusions and high saline enemas. Stimulants such as strychnin, caffeine and theobromin would produce stimulation with diuresis. Ammonia and oxygen inhalation may be used to supply the alkalines and to aid in oxidation. Sodium iodid and alkaline waters would aid in reducing viscosity of the blood and the medicinal treatment may be supplemented by applying heat to the body and extremities.

Credit is hereby given and our sincere thanks extended to Professors Lee, Scott and Pike for their kindly assistance and advice tendered in these researches, which were made in the physiological laboratory of the College of Physicians and Surgeons, Columbia University, New York, also to Mr. Edward Burchell, for his kind assistance in preparing and mounting the microscopic specimens and to Drs. Dixon and Holden for their kindness in examining our specimens.

47 West Fifty-First Street—103 East Eighty-First Street.

ABSTRACT OF DISCUSSION

DR. WARD A. HOLDEN, New York: The clinical symptoms following the inhalation of wood alcohol are so identical with those following its imbibition that it was to be expected that laboratory experiments would give the same results in each. The defense in a recent suit for damages was based on the fact that there was in the literature no experimental proof that the inhalation of wood alcohol could cause blindness. The proof has now been supplied by this painstaking investigation, and an inspection of sections of the retinas of animals so poisoned reveals the same degeneration of the ganglion cells that I found a dozen years ago in animals after the imbibition of wood alcohol. When hundreds of thousands of dollars are invested in an industry it naturally is difficult to bring about safeguards and restrictions that might in any way diminish the sales of the product. The New York Committee for the Prevention of Blindness of which I am a member, believes that in time something may be accomplished. The subject was studied at some length and then a campaign of education was started in the lay press which it was hoped would render it easier to secure the legislation we desired. Hundreds of newspapers took up the matter and many trade journals treated it editorially. The varnish trade and the brewers especially were favorable. We were attacked chiefly by the perfumery-trade journals, which was to be expected, since the great majority of perfumes and toilet preparations are made up with wood alcohol. The National Brewers Association asked us to furnish them an exhibit for their last annual meeting and they sent out to the brewers of the country some thousands of reprints of our literature. For several years past suits for damages for blindness or death in varnishers in the brewery vats have been uniformly successful, and in the last case of which I have knowledge a man in Brooklyn whose eyesight had been impaired received \$12,000 from a brewing company in settlement of his claim because they feared to have the case go to a jury. Our efforts to have wood alcohol and preparations containing it labeled poison have failed in the New York state legislature and in the New York City Board of Alder-

men. The New York Department of Health, however, of whose advisory council I am a member, is about to add an ordinance to the sanitary code to prevent the use of wood alcohol in any preparation intended for internal or external use by man, and to have wood alcohol and its preparations bear the regulation poison label. The suggestion has been made in the paper that a specially denatured grain alcohol, without benzin or pyridin, be permitted to be used in the preparation of varnishes. This would seem to be a good suggestion. The denatured grain alcohol statute has almost entirely failed of its intended purpose. Denatured alcohol has not come into general use as a cheap and relatively harmless solvent, because of the restrictions thrown about its sale and of the necessity of using denaturing agents which render it more or less unfit for use in certain industries, so that the more expensive and more toxic wood alcohol, sold everywhere without restrictions, is generally used.

DR. HIRAM WOODS, Baltimore: The difficulty in securing the conviction of persons selling wood alcohol is great everywhere. This past winter I had an experience with a man blind from wood alcohol. There was no difficulty in procuring the liquor and showing that it contained 30 per cent. of wood alcohol, sold as Sherwood whiskey. The man who sold it was arrested. The Maryland law provides that anyone who sells wood alcohol to be used as a beverage is guilty of a misdemeanor. The Italian liquor-dealer said he bought it from a jobber and had not himself put the wood alcohol in. Then the judge decided that since the saloonkeeper had said he had not done it, it was up to the State Board of Health to hunt up the jobber and trace it back. This was impossible. The man was acquitted. We should have the legal department of the American Medical Association prepare us a model law. It is a state matter, of course, but it is extremely difficult to get a law fixed without some flaw that leaves these rascals out.

EDGAR B. BURCHELL, New York: On Dr. Schoenberg's suggestion I made an investigation of the blood-count of a rabbit at various intervals after it had been given 8 c.c. of methyl alcohol subcutaneously. The results are shown in the accompanying table. You will see there is quite a difference between the blood picture of the rabbit and the dog. There was no ocular effect at all in the rabbit. By careful physical examination of the rabbit there were no discernible changes in the physical signs. The findings are based on cell-counts of 500 in each instance.

DR. M. J. SCHOENBERG, New York: We have observed in our animals continuous movements of the head together with uncertain gait which we think are due to some changes in the internal ear, and for that reason I think it would be worth while in a case of such poisoning for some otologist to examine the function of the internal ear, which has never been done before. Another point is that rabbits exhibit greater resistance than dogs to wood-alcohol poisoning by either inhalation or imbibition, which agrees with the findings of Reid Hunt. The findings of Dr. Burchell would explain this somewhat. A dog placed in a box with 5 or 10 ounces of wood alcohol will become unconscious and remain so from twenty-four to forty-eight hours or more. A rabbit resists this. The changes in the blood of the dog compared with those in the blood of the rabbit explain partly why the dog is more sensitive than the rabbit. I think the most important point is the post-mortem findings in animals as compared to

human beings after wood-alcohol poisoning. I had the fortune to be present at a post-mortem on a girl who had drunk liquor containing wood alcohol and died thirty-six hours later. The post-mortem findings were almost exactly the same as in the animals—dogs and a monkey—namely, congestion of the brain, some meningeal hemorrhages, empty heart, hemorrhages in the pleura and pericardium, congestive patches and hemorrhage in the stomach. The patient also complained of impaired hearing several hours before she died.

The examination of the intra-ocular pressure might also help in the prognosis of these cases. We found in the dog that whenever the intra-ocular pressure, after the administration of wood alcohol, is below 5 mm. mercury, the dog died within twenty-four hours. I think that is a point to be considered in wood-alcohol poisoning.

There are two and a half million men working in industries which make and use wood alcohol and I think that there are quite a few of them suffering from the consequences of daily inhalation of wood alcohol. The clinical picture of this occupational disease has not yet been worked out. Judging from our experiments, the clinical symptoms would be nausea, vomiting of blood, headaches, disturbance of vision produced by slight toxic edema of the retina and optic nerve, and they ought to be looked for, together with some changes in the blood. I do not know any one who has made a systematic examination of the blood in such patients.

The greater acidity of the aqueous humor, as compared with that of the serum, after inhalation of wood alcohol is of considerable interest, since this apparent contradiction throws some light on the secretory function of the ciliary body. In view of the facts brought out by this paper, the sale of wood alcohol must be prohibited entirely for the external as well as for the internal use on the human body. I see no reason why wood alcohol should be kept and sold in drug-stores, where people buy it in good faith that it is a "tonic" when used as a rub.

A STUDY OF THE ARNETH FORMULA*

GRAHAM E. HENSON, M.D.

JACKSONVILLE, FLA.

Since Arneth¹ in 1904 suggested his classification of polymorphonuclear neutrophils as a guide in the prognosis of infectious diseases, while there have been a number of contributions by other authors, their work in applying the classification has been largely confined to tuberculosis, although Kagan² has reported his findings in cases of sepsis. In the Arneth classification the polynuclears are divided into five classes depending on the number of nuclei contained within the cell. Taking the blood from a large number of healthy persons he determined that in the normal person a fairly constant relative percentage of the cells was found in each of the five columns (Table 1). An

Percentage	5	35	41	17	2

increase in Columns 1 and 2 with a corresponding decrease in Columns 3, 4 and 5, he termed a shift to the left, the normal Arneth index, comprising the totals of Columns 1 and 2, being 40.

* Read before the Section on Practice of Medicine at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.
1. Arneth, Joseph: Die neutrophilen weissen Blutkörperchen, Jena, 1904.
2. Kagan, S. H.: Nuclear Classification of the Neutrophil Leukocytes and Its Relation to Disease, Boston Med. and Surg. Jour., 1910, clxii 709.

Bushnell and Treuholtz³ adopted the method of adding one half of the number contained in Column 3 to those in Columns 1 and 2. In the series which I now report I have preferred to take as an index the number in excess of the normal count in Columns 1 and 2; thus, a total of 50 in these columns is reported as plus 10. In classifying the neutrophils I have adhered to the rules set by the majority of previous investigators, nuclei being joined by a thread being counted as two, while those connected by a distinct isthmus were counted as a single nucleus. The greatest care has been maintained to avoid the counting of superimposed nuclei, which would result in causing a false shift to the left; when it was extremely difficult to determine with any certainty the column in which to place a cell, it was discarded. In making the differential counts, two hundred cells have been counted, and a similar number of polynuclears used in arriving at the Arneth formula. Wright's stain has been used in all instances with satisfactory results. To facilitate the technic in securing the differential count and Arneth index at the same time, a pad ruled as in the accompanying blank form was used.

1	2	3	4	5

Polys.	Large Lymp.	Small Lymp.	Large Mono.	Eosin.	Baso.	Trans.

Blank form used in recording differential count and Arneth index.

As the white cells are counted a check is placed under the proper heading, the polynuclears put in their respective columns, according to the number of nuclei, with a total of 200 cells counted, the differential count determined and a sufficient additional number of polynuclears counted to bring their number to 200, thus arriving at the Arneth index.

In Series A (recorded in Table 2), consisting of thirty-one unselected cases taken from the surgical service of Dr. Raymond C. Turck at St. Luke's Hospital, a total and differential white cell-count is not recorded. Cases 2, 5, 6, 9, 12, 13, 14, 18, 19, 20, 21 and 27 all showed decided shifts to the left. All of these were septic cases excepting Cases 6, 14, 21 and 27, Case 6 being a case of trifacial neuralgia in an unhealthy person, Case 14 one of exophthalmic goiter, Case 21 a compound fracture of the tibia accompanied by severe shock, and Case 27 a clean hernia, the latter showing a very decided eosinophilia; but the patient escaped from observation before further investigation of a possible causative factor could be conducted. In Case 18, epithelioma of the lower jaw with a plus index of 7.50, the patient succumbed a few weeks after admittance. The other nineteen cases in this series showed practically normal indexes, all of them clean surgical cases excepting Case 4 with a superficial sepsis recovering in two weeks, Case 8, a case of multiple fistulas recovering in three weeks, and Case 22, a case of cancer of the penis showing no recurrence eight

months later. In contradistinction to the pictures in these cases attention is called to Cases 2, 5, 9, 12, 13 and 20, all of which had decided plus indexes and a slow convalescence.

Series B also consists of forty-two cases from the surgical service of Dr. R. C. Turck. The clean surgical cases only serving as a control were not used after a sufficient number had been obtained for this purpose. This series is, then, largely from selected cases. Table 3, the record of cases in Series B, in addi-

after operation. Cases 1, 6, 18, 27 and 40, in which there was no shift, were of a nature that would lead us to expect one. It is significant, however, that three of these are in children, which, together with the blood-picture in Case 20, an infant, indicates that the Arneth formula, like the general blood-picture, is subject to a wide variation in infants and young adults.

In a further series of twenty-five cases of pulmonary tuberculosis I have been able to confirm the findings of Arnold C. and Henry Klebs,⁴ Minor and Ringer⁵

TABLE 2.—RECORD OF CASES IN SERIES A

Case No.	Age	Diagnosis	Treatment	Disposition	Arneth Count					
					1	2	3	4	5	Shift
1	7	Fracture of femur.	Lane plate; primary union.....	Cured	4.5	36.5	42.0	14.5	2.5	1.0
2	33	Septic cholecystitis.	Cholecystectomy, followed by infected wound in adipose tissue.	Cured, convalescence 2 months.	11.5	36.0	40.5	11.0	1.0	7.5
3	41	Ventral hernia ...	Intestinal resection; end-to-end anastomosis; repair of hernia.	Cured	8.0	27.0	50.0	12.0	3.0	...
4	50	Multiple stab-wounds, head, face, back and pleura; several infections.	Repaired by suture; drainage.....	Discharged cured in 2 weeks.	5.5	34.0	44.0	13.5	3.0	...
5	27	Ruptured appendicular abscess; general peritonitis.	Drainage; proctoclysis	Discharged cured in 6 weeks.	10.0	38.5	37.0	13.5	1.0	8.5
6	65	Facial neuralgia...	Deep injection of alcohol.....	Discharged improved in 4 weeks.	14.0	32.0	46.5	5.5	2.0	6.0

9	45	Rectal fistula; ischiorectal abscess.	Radical treatment on 4 occasions..	Discharged cured in 8 weeks.	14.5	34.5	38.0	12.0	1.0	9.0
10	7	Fracture of femur clavicle.	Splints and plaster dressings.....	Cured	8.0	27.0	46.0	15.0	4.0	...
11	40	Hemorrhoids	Radical operation	Cured	8.5	28.5	46.0	12.5	4.5	...
12	38	Left inguinal hernia; appendicular abscess.	Radical operation for hernia; drainage of abscess.	After draining pus 5 weeks, discharged cured.	20.5	29.0	37.5	11.5	1.5	9.5
13	33	Multiple urethroscrotal fistulas.	Incision, resection, drainage, etc....	Discharged cured in 5 weeks.	19.0	34.0	32.5	9.0	5.5	13.0
14	42	Exophthalmic goiter.	Radical operation; primary union..	Cured	14.0	37.5	37.0	9.5	2.0	11.5
15	33	Fracture of femur.	Splints and plaster dressings.....	Cured	9.0	28.0	47.0	12.0	4.0	...
16	35	Appendicitis; Lane's kink.	Appendectomy; adhesions broken..	Cured	6.5	34.0	41.0	12.0	6.5	...
17	43	Fibroid uterus....	Hysterectomy	Cured	8.0	28.5	48.0	12.0	3.5	...
18	35	Epithelioma superior and inferior maxillaries.	Curet and cautery.....	Died 4 weeks later.....	10.5	37.0	41.0	9.0	2.5	7.5
19	33	Gangrenous appendix.	Radical operation	Cured	15.0	34.0	41.5	7.0	2.5	9.0
20	36	Empyema gall-bladder.	Cholecystectomy	Discharged cured in 3 months.	21.0	39.0	34.0	5.0	1.0	20.0
21	20	Compound fracture tibia; multiple superficial injuries.	Lane plate	Cured	19.5	28.5	37.5	10.5	4.0	8.0
22	68	Cancer of penis..	Amputation	No recurrence 8 months later.	7.0	28.0	48.5	13.0	3.5	...
23	35	Ventral hernia and fecal fistula.	Intestinal resection, 7 feet 5 inches of intestines.	Improved	6.0	23.5	44.5	19.0	7.0	...
24	2½	Fracture of humerus.	Splints and plaster dressings.....	Cured	9.5	33.5	48.5	6.0	2.5	3.0
25	24	Compound fracture of tibia.	Bone graft; primary union.....	Cured	17.5	27.5	45.5	7.0	2.5	5.0
26	12	Hypospadia	Plastic operation.....	Cured	9.0	30.5	45.5	12.0	3.0	...
27	12	Inguinal hernia; hydrocele cord; scrotal hydrocele.	Radical operation	Cured	16.0	44.5	34.0	5.5	.0	20.5
28	53	Inguinal hernia...	Radical operation	Cured	13.5	26.5	50.5	7.5	2.0	...
29	30	Perineorrhaphy and trachelorrhaphy.	Radical operation	Cured	7.5	29.5	51.5	9.0	2.5	...
30	11	Lacerated hand..	Repair of tendons.....	Cured	6.0	32.5	45.5	12.5	3.5	...
31	34	Fibroid of uterus.	Hysterectomy	Cured	9.5	31.0	46.0	10.5	3.0	...

* In Case 13 the patient was colored; all the others were white persons.

tion to giving the Arneth index, records the total white cell and the differential counts. Cases 2, 7, 8, 11, 13, 17, 19, 20, 22, 23, 25, 28, 29, 30, 31, 32, 35, 36 and 37 all show decided shifts to the left. All of them were septic cases excepting Cases 20 and 22, Case 20 being an inguinal hernia in an infant 2 years old, and Case 22 a carcinoma of the stomach, the patient deserting and being lost to observation. In the series, Cases 7, 24, 31 and 35 with plus indexes of 38, 3, 30 and 18.5, and Case 42 with a normal index, succumbed shortly

and Cummings,⁶ in which they found a decided shift to the left in unfavorable cases.

* In Cases 3 and 22 the patients were colored; all the others were white persons.

In a smaller series of typhoid fever cases I also found a shift to the left in severe infections, while in malaria fever and pellagra there seems to be no change from the normal Arneith picture. I hope to have the opportunity to report in detail on this work at some future time. My findings up to the present would lead me to think that in certain classes of cases the Arneith index is of some prognostic value, enough so at least to warrant a careful and intensive study of the blood-picture in all septic and infectious diseases.

I wish to acknowledge my deep appreciation to Dr. Raymond C. Turk, chief surgeon of St. Luke's Hospital, for the privilege of studying the blood of his patients, and for many other courtesies extended to me while the work was in progress.

THE DESICCATION TREATMENT OF CON- GENITAL AND NEW GROWTHS OF THE SKIN AND MUCOUS MEMBRANES*

WILLIAM L. CLARK, M.D.

PHILADELPHIA

I have undertaken during the past six years some experimental and clinical studies with high-tension electric currents, for the purpose of determining their value relative to the reduction of congenital and neoplastic growths. The practicability of utilizing such currents for producing a thermic action of just sufficient intensity to devitalize tissue by dehydration was described by me before another section¹ of this association in 1912. This method has been developed to a higher degree of efficiency since that time, and additional facts concerning it realized. It has proved so satisfactory in my hands that I take the liberty of again calling attention to it and of presenting a series of pictures to show some of the results obtained.

The field of application is limited to accessible neoplasms, as of cutaneous surfaces and such mucous membranes as the mouth, throat, larynx, conjunctiva, bladder, urethra, vagina, uterine cervix and rectum.

The advantages of desiccation are as follows: 1. Accessible abnormal tissue may be destroyed rapidly and effectively and the operation is bloodless. 2. It is a method of precision. A small point may be destroyed without infringement on normal tissues, as may an area of large size and considerable depth. 3. No needle or other instrument is inserted into the growth. 4. The current has an anesthetizing property, which renders application bearable. 5. There is a devitalizing action on cells of less vitality than normal cells somewhat deeper than the desiccated area, leaving the normal cells intact. 6. There are sterilization and rapid repair. 7. Blood- and lymph-channels are sealed,

which lessens the likelihood of metastasis in cases of malignancy. 8. The cosmetic result is good, as shown by the absence of contracted cicatricial tissue.

There are no disadvantages, other than the expense and cumbersomeness of necessary apparatus.

THE DESICCATION METHOD

Heat effects as applied to living tissue range in degree from simple hyperemia to carbonization. Somewhere between these extremes there is a point the effect of which is more than hyperemia and less than carbonization, which is called the desiccation point. If this accurate caloric degree is produced, controlled and sustained, it will cause rapid dehydration of the tissue desired to be devitalized, rupturing the cell capsule and transforming it into a dry mass; in other words, just enough heat is generated to destroy tissue without actually carbonizing it. Substances such as soap, potato and tissues, cadaveric and living, may be desiccated through a sheet of white paper without charring or discoloring the paper, and the transformed matter pulverized between the fingers. The correctness of the desiccation principle has been acknowledged by physicists, and I claim for it a new principle for application to surgery.

Instrumentation.—Static apparatus, twenty-four plates, twelve made of fiber 33 inches in diameter, and an output of, at least, 3 milliamperes of current, and twelve of glass 38 inches in diameter. Five horsepower motor to propel fiber plates, these plates being capable of approximately 2,000 revolutions a minute. Two Leyden jars, each of 0.00042 microfarads' capacity, used in conjunction with a resonator or surge-coil, the inductance portion of which has forty turns $3\frac{1}{2}$ inches in diameter, of 25 gage Brown and Sharp copper wire. The surge end of the coil has ninety turns of the same size wire, same diameter of turns. These careful measurements are necessary for a proper balance between the capacity, inductance and the resistance.

Technic.—A Leyden jar is connected with each pole of the machine. The resonator or surge-coil is interposed between them and connected with each jar, thus completing the circuit. One end of the resonator is grounded. A wire is carried from the side of the resonator not grounded to the desiccation applicator. This applicator is supplied with a make-and-break device by means of which the current is controlled at will. A fine needle is inserted in the end of the applicator and kept in place by means of a thumb-screw. The speed of the plates, which controls the current strength, is regulated according to the size and depth of the area desired to be destroyed. This is not done by set rule, but by knowledge gained from technical experience. The rods of the static machine are then separated until the discharge of sparks assumes a characteristic formation, which is known as the point of critical resistance. The patient should lie on a low operating-table or reclining-chair. The operator sits and rests his elbow against the side of the table with his wrist on the part of the patient adjacent to the area to be treated, to insure a steady hand. For superficial dehydration, the needle-point is not brought in direct contact with the tissue, but an air-space varying from 0.25 cm. or less to 2 cm. is interposed between them. The electron waves are thrown from a metal point and projected to the tissue in the form of a fan-shaped

efflux of sparks following one another with such rapidity that to the eye the appearance is that of a luminous glow. When deep destruction is desired, the patient is grounded and the needle is brought in direct contact with the tissue. The placing of the operator's hand on the patient at a point opposite the area under treatment adds to the capacity, and helps to concentrate the current; this is usually sufficient without grounding. It matters not which pole is used, as this current is unlike the galvanic current, which has electrolytic or chemical properties, and polarity must be considered, whereas the desiccation current from either pole is purely thermic in action. The unaltered current from the static machine cannot be used for desiccation, but it must undergo a physical transformation analogous to the metamorphosis of a volume of water into spray or steam. This is done by introducing into the circuit the Leyden jars and resonator as described.

DIFFERENTIATION BETWEEN DESICCATION AND OTHER ELECTROSURGICAL METHODS

1. Desiccation (Clark).
2. Electrolysis; synonyms, ionic surgery, cataphoresis (Massey).
3. Fulguration (DeKeating Hart), non-destructive.
4. Diathermy (Nagelschmidt), synonyms, thermopenetration, thermocoagulation.
5. Fulguration (destructive); synonym, high-frequency cauterization.

1. Desiccation (Clark) devitalizes by dehydrating the tissues.

2. Electrolysis destroys tissue by the chemical or electrolytic action of the galvanic current.

3. Fulguration (DeKeating Hart) does not directly destroy tissue, but it is asserted that when long high-tension sparks are applied to the field in malignant disease after radical operation, alteration of nutrition of the part ensues, preventing the proliferation of cancer-cells. It is also declared that the percentage of recurrences is less than with operation alone.

4. Diathermy (Nagelschmidt) is produced by the bipolar d'Arsonval current. It may be used for simple heating of the tissue or it may be carried to the point of destruction, in which case the tissues are cooked. No sparks are used by this method, but two electrodes are brought into direct contact with the tissue, the position of the indifferent electrode depending on the direction in which the heating or destruction is desired. The current flows in both directions, and meeting with resistance in the body, completing the circuit, heat is generated in the tissues.

5. Fulguration is produced by the high-frequency current. The term "fulguration" is derived from the Latin word "fulgur," meaning lightning or spark.

an induction coil and desiccation from a high potential static apparatus.

DIFFERENTIATION BETWEEN THE PHYSICS OF DESTRUCTIVE FULGURATION AND DESICCATION

While the current generated from a coil or other magnetic device, and transformed by proper accessories, is capable of producing a coarse destructive action, the current from such a source has insufficient frequencies or oscillations, and is incapable of producing the refined desiccation effect, on account of the interruptions in the primary of the coil. As no discharge can be transmitted to the body until such interruption occurs, the current is delivered in a series of hot discharges, which renders the thermic degree inconstant, and the impact against the tissue painfully severe. A steady flow of current as is produced from the static machine is necessary, but it must be of large capacity and subject to control, or it will fall short of or go beyond the desiccation point. The destructive effect on tissue produced by the coil type of current may be compared to a surgical operation with a saw-edged knife, while the devitalizing effect produced with the static type of current may be likened to the more refined action of a keen-edged bistoury.

EFFECTS OF DESICCATION

The size and depth of the area that may be desiccated with one application is controlled by the operator and depends on the following six factors: (1) current strength; (2) whether monopolar or bipolar; (3) frequency of oscillations; (4) distance of the electrode from the body; (5) time of exposure, and (6) density of tissue.

Desiccation is usually, but not always, contra-indicated in neoplasms that are covered by healthy skin, as the skin must also be destroyed to reach the diseased tissue. Desiccation destroys tissue without opening blood- or lymph-channels, and will act as a styptic when there is oozing of blood. It sterilizes tissues on which it acts directly, as has been shown by experimentation with cultures taken before and after treatment of an infected area of tissue. A dry crust forms at once after the application, and the time required for separation depends on the character of the tissue. In the case of mucous membranes the desiccated tissue soon becomes macerated by the secretions and may separate in a few hours, while on the skin surface it takes a longer time. When the skin is soft and vascular there is more rapid separation than when it is hard and with poor blood-supply. Thus, a soft mole will slough more readily than a callus. Regeneration of skin or scar tissue often takes place underneath the crust. The procedure is not entirely painless, but quite bearable if the technic is correct. The current, applied gently at first, has anesthetizing properties. It is usually sufficient, but in supersensitive persons a local anesthetic is employed in addition, either by topical application in the case of mucous membranes and ulcerated surfaces, or by infiltration if the area is extensive and deep, although the latter is never practiced when there is a suspicion of malignancy; cocaine is driven into the tissue by positive galvanism is used in preference. In rare cases a general anesthetic is employed. Nitrous oxid gas and oxygen is used in preference, although chloroform may sometimes be employed. Ether should never be considered on account of its inflammable properties.

CONDITIONS FOR WHICH DESICCATION IS
APPLICABLE

Verruca, Moles, Roentgen-Ray and Senile Keratosis.—Usually one application is sufficient in these conditions. The lesion is immediately transformed into a dry crust. It was my practice formerly to allow this crust to remain until it separated naturally, but it has recently been found that it is an advantage for immediate cosmetic reasons and more rapid healing to remove the crust at once with a groove director, or some such instrument. The base of the lesion is then sealed by superficial desiccation, and the thin ensuing crust separates in a few days. Healing is rapid, and the area, which is at first slightly red, gradually fades to normal color. There is no contracture as is usually the case with cauterization, but a smooth surface results. It is justifiable to advise the removal of these growths for other than cosmetic reasons, as they may be considered precancerous lesions.

Nevus Pigmentosus and Vascularis, Lentigo, Chloasma, Tattoo Marks, Coal Marks, Etc.—In these conditions the technic is the same as in the preceding, and the results have been quite satisfactory. In large port-wine marks and pigmented nevi I have found the ultraviolet ray produced by the Kromayer quartz-mercury lamp more satisfactory.

Keloid.—Desiccation followed by the Roentgen rays has been found to be a successful treatment. The same results may be obtained by the Roentgen rays alone, but a longer time is required. It has been observed that a better cosmetic result is obtained by desiccation followed by the Roentgen rays than by excision and the Roentgen rays.

Neoplasms of the Hollow Viscera.—Bladder: Employing a catheterizing cystoscope under the usual aseptic conditions, the urethra is anesthetized by a 2 per cent. cocain solution, or some other local anesthetic, and the bladder distended with sterile water or boric acid solution. A wire insulated to the end is then passed through the instrument and brought in direct contact with the growth, which may be destroyed in one, or a series of applications, depending on its size. The current and destructive action is always under the control of the operator. Recent experience justifies the hope that in selected cases desiccation may be of service in prostatic hypertrophy, treated by the urethral route.

Urethra: Papilloma, Caruncle, Granulations, Infected Glands, etc.: A thin insulated wire is passed through the treatment aperture of an air-inflation or other urethroscope, as is done with the applicator in making topical applications. Papilloma, caruncle, chronic granulations and infected glands following Neisserian infection, or other causes, may be destroyed, and there is sterilization somewhat deeper than the area destroyed because of heat penetration. The advantages of this treatment over the cautery and chemical escharotics are absence of much inflammatory reaction and no contracted cicatrix, and hence less likelihood of stricture.

Rectum: Hemorrhoids, Papilloma, Granulations, Ulcerations, etc.: External hemorrhoids and growths near the rectum may be very satisfactorily treated by desiccation, and growths in the rectum when a suitable proctoscope is used to render the lesion accessible. Operation is usually to be recommended in extreme internal hemorrhoids in preference to desiccation, but should there be a contra-indication to operation, even these may be successfully treated by desiccation.

Larynx: Tumors of the larynx may be destroyed by desiccation. The laryngoscope or the ordinary laryngeal mirror may be employed to expose the interior of the larynx, and the current applied by means of an insulated wire suitably curved. It is essential to success in these cases to destroy all reflexes in the throat with a strong solution of cocain; otherwise the application of the current will be impossible.

There is reason to hope that with improved endoscopes the future may show desiccation to be applicable to some neoplasms in the esophagus and stomach.

Throat and Pharynx: Neoplasms in these regions are quite accessible, and may be destroyed by desiccation. Mucous membrane growths respond readily. The whole or a portion of diseased tonsils may be desiccated without causing bleeding, and the operation is made bearable by applying a solution of cocain of sufficient strength. Desiccation has no particular advantage over excision in tonsil work, but should there be a refusal or contra-indication to operation, then desiccation may be relied on as a worthy substitute. In young children operative measures are to be recommended in preference to desiccation in throat conditions, because a general anesthetic must be used. Chloroform in the presence of unusual heat gives off hydrochloric acid and chlorin fumes, and ether is contra-indicated on account of its inflammability.

Nose.—Growths in the anterior nares, such as polyps, angiomas, papillomas and epitheliomas are accessible, and are usually successfully treated by desiccation.

Eye.—Desiccation may be applied externally to the lids for such lesions as xanthoma, verruca, nevi and epithelioma, and to the conjunctiva for trachoma, dry granular conjunctivitis, papilloma, ulcerations and pterygium. There is little danger in working near the eye, as the control of the desiccation current is perfect.

APPLICATION OF DESICCATION IN MALIGNANT
DISEASE

1. *Cutaneous Surfaces.*—(a) *Localized:* Desiccation in my hands has been almost uniformly successful in localized epitheliomas and rodent ulcers of the skin. The destruction is carried beyond the diseased area for a short distance to insure thorough eradication. Blood- and lymph-channels are sealed, on account of which there is less likelihood of metastasis. Healing is rapid, and the cosmetic effect excellent. When a large area is involved a short course of Roentgen-ray treatments following desiccation is advisable, taking advantage of their well-known selective action on cancer-cells, lest there be some disease that possibly escaped desiccation. This may not always be necessary, but it is wise to take advantage of this combination treatment. As much can be immediately accomplished by one desiccation application as can be accomplished by the Roentgen rays alone in a comparatively long period of time, and desiccation will cure cases that the Roentgen rays alone will not affect, but in combination the efficiency of both is increased.

(b) *With Metastasis:* The results in these cases are usually unsatisfactory by any method, and no claims are made for desiccation except in conjunction with radical operative measures, when the field may be desiccated after operation in suitable cases, to seal blood- and lymph-channels. It is a duty as a routine measure to treat postoperatively with the Roentgen

rays as the best means of preventing recurrence, promoting comfort to the patient and prolonging life.

2. *Mucous Membranes.*—(a) *Localized:* In localized cancer of the mucous membranes, such as the tongue, and the buccal surfaces or the lip, the results of desiccation compare favorably with those obtained in localized skin cancers, although there is not quite the same assurance of success, on account of greater proneness to metastasis and because one cannot be sure that the adjacent glands are not involved, even though they may not be palpable.

(b) *With Metastasis:* This is the most hopeless class of cases with which the surgeon has to deal, and there is much to be desired with any treatment known at the present time. Desiccation is used only as a palliative. Unless too far advanced, the chance of possible success afforded by radical operation or desiccation followed by the Roentgen ray should not be denied the patient.

3. *Inoperable Cancer.*—In absolutely inoperable cases, whether of the skin or mucous membranes, the initial lesion may be desiccated and massive Roentgen-ray dosage applied to the glands and desiccated site. Some unexpected good results have shown that this course is sometimes justified. In cancer of the cervix and rectum, if inoperable, desiccation as a palliative means has advantages over the curet and cautery, for the reasons that a general anesthetic is unnecessary, there is less inflammatory reaction, it destroys the accessible diseased tissue quite as effectively, sterilizes, deodorizes and will stop bleeding.

4. *Postoperative Recurrences.*—Desiccation has a field of usefulness in postoperative recurrences in any location that is accessible. For example, recurrence along the line of excision in cancer of the breast may sometimes be controlled by this method, or at least act as an excellent palliative.

5. *Sarcoma.*—In accessible sarcomas, if seen early, desiccation is a satisfactory treatment. One extensive melanotic sarcoma of the forearm, confirmed by pathologic examination, which was excised, recurred in a short time and was desiccated. There has been no recurrence at the points treated for two years, but several new foci appeared at various times, which were all controlled by desiccation. In advanced sarcoma the same general rules apply as in advanced carcinoma.

Miscellaneous conditions in which desiccation has been used with success are: early Paget's disease, lupus vulgaris and erythematosus, acne vulgaris, hypertrophic acne rosacea, adenoma sebaceum, chancroids, condylomas, clavus, varicose and other ulcers with exuberant granulations, growths and granulations on the tympanum.

SUMMARY OF INDICATIONS

1. Desiccation is a successful treatment for all accessible benign neoplasms or lesions of the skin and mucous membranes in which destruction of tissues and good cosmetic result is desired. All of such lesions may be regarded as possibly precancerous.

2. Desiccation is curative in the great majority of localized malignant lesions of the skin and mucous membranes. In the more advanced cases the efficiency is increased by combining it with the Roentgen rays, attention being paid to accurately measured dosage.

3. Desiccation is only palliative in cancerous lesions associated with glandular metastasis, in postoperative

recurrences and in cases too far advanced for operation. The use of desiccation and the Roentgen rays in some of these cases is justifiable, because sometimes good results beyond expectations are obtained.

I have endeavored to present the important features of this method, covering the various fields of application as briefly as possible, and it is hoped that the presentation is sufficiently comprehensive to serve as a basis for others who may desire to take up the work.

1809 Chestnut Street.

ABSTRACT OF DISCUSSION

DR. JAY F. SCHAMBERG, Philadelphia: Desiccation is a valuable method in appropriate cases of various cutaneous growths. Many of these conditions, as we know, are quite amenable to other methods of treatment long employed by dermatologists. For example, angiomas, in most cases, can be satisfactorily removed by carbon dioxid snow. I believe the method described by Dr. Clark, however, is very valuable in cancer of the mucous membranes of the nose and mouth, particularly the latter, which often proves unsatisfactory to other methods, including surgical procedures. From what I have seen in Philadelphia of the results of the desiccation and fulguration method, I believe it is perhaps the best one I know of in the treatment of cancer of the mouth, and is preferable in many cases to excision. It has a very excellent field of usefulness in the treatment of cutaneous growths, although there are many other physical agents that are equal and some, perhaps, superior to it for the removal of superficial lesions. In a few of the cases I have seen, fulguration has produced an unnecessarily extensive destruction of tissue, more so than would follow other well-chosen methods. These cases, however, had not been treated by Dr. Clark. It might be well for others to emulate Dr. Clark and perfect the technic of this method of treatment, which appears to have a distinct field of usefulness.

DR. H. H. HAZEN, Washington, D. C.: One disadvantage is that in these cases it is impossible to obtain a specimen for pathologic study, so that the true character of the lesion can be determined. We know that with the prickle-cell type of epithelioma, metastases are very apt to occur, while with the basal-cell type they are very rare, and we need statistics on the ultimate results in these cases, based on pathologic examination.

DR. C. A. SIMPSON, Washington, D. C.: How does Dr. Clark get his selective action by this fulguration method? Does he compare it with the selective action of the Roentgen ray or radium?

DR. W. H. SCHMIDT, Atlantic City: I have had some experience with this method, and have recently employed it in two cases of cancer of the throat. In the first case, in which the disease was well advanced, the pain was relieved after two or three applications of the desiccation method. In the second case, which is still under treatment, the outlook is favorable. The disease is not so far advanced as in the first case, and not only has the pain been relieved, but also the ulcerated surface has a much healthier appearance, and the discharge has lessened. I have also found the method of value in infected and painful ulcers of the leg.

DR. ARTHUR F. HOLDING, New York: Radium is expensive and difficult to obtain, and so far as I have been able to ascertain, the method of treatment described by Dr. Clark is applicable to the same class of cases as is radium, and inasmuch as many practitioners cannot obtain radium, while this apparatus and method of treatment, on the other hand, is within their reach, it is a very valuable addition to our armamentarium. Of course, radium may possess certain properties or advantages of which we are now ignorant, but so far as we know at present, its usefulness in skin diseases is now limited to a class of cases approximately similar to those reported by Dr. Clark. The apparatus necessary to apply desiccation is much more readily obtainable than radium, and up to the present it seems to have produced equally good results in the treatment of various skin growths, and in less time.

DR. WILLIAM L. CLARK; Philadelphia: Dr. Schamberg referred to the unnecessary destruction of tissue by the fulguration method in some of the cases that came to his notice. I wish to again emphasize the fact that fulguration and desiccation are separate and distinct methods. With desiccation, in experienced hands, there is no unnecessary destruction of tissue in any case, as the operator has complete control, even to the smallest discernible point. The reason sections for pathologic study were not taken in many cases is due to the fact that such a procedure, to a certain extent, would defeat the object of desiccation, which is to destroy tissue without opening blood- and lymph-channels. In apparently clear cases this risk is not taken; in doubtful cases sections have been taken and the channels immediately sealed by desiccation. Desiccation will destroy normal tissue quite as readily as malignant tissue if brought in direct contact, but the point made, an explanation of which was asked for, is that malignant tissue appeared to have been destroyed and had disappeared at points deeper than those actually primarily destroyed by desiccation. This is probably explained by the fact that abnormal tissue is of lower vitality than normal tissue, and that the heat penetration was sufficient to cause the death of the diseased cells, with recovery of the normal cells. In this way it does compare with the selective action of the Roentgen ray and radium. The desiccation method of treatment is applicable to other conditions besides skin lesions. It has been successfully used for neoplasms of such accessible mucous cavities as the larynx, bladder, vagina, rectum and urethra.

THE DIET IN TYPHOID FEVER*

LEWELLYS F. BARKER, M.D.

BALTIMORE

Whether fever patients shall be fed liberally or sparingly is an old question. Most of us were brought up on the adage, "Stuff a cold and starve a fever," though long before our time Graves¹ had advocated a liberal diet and had suggested that should his friends after his death seek a suitable epitaph for his grave they might use the words, "He fed fevers." In typhoid fever especially it was almost a universal practice to limit the diet to fluids and to a low caloric intake. Emaciation was believed to be inevitable in typhoid fever. Losses of weight as great as 30 or 41 per cent. (Curschmann²) have been recorded in extreme instances. Complications increased the loss of weight (Lorain³), but even on a diet of 2,600 calories per day in an ordinary case the weight may decrease by as much as 20 pounds (Purits⁴). The disinclination of the patient to take food was considered an indication that he did not need food. Further, it was supposed that food substances could not be well digested and assimilated in the course of high fever; and it was believed that the risks of hemorrhage and perforation were enormously increased in typhoid if solid foods were given. Finally, aside from the difficulties and dangers mentioned above, it was thought that in fever there is either (1) toxic destruction of protein which makes the maintenance of nitrogen equilibrium impossible even if the protein intake and the total caloric intake be as high or higher than is necessary to maintain weight and nitrogenous equilibrium in health (F.

Müller,⁵ Kraus), or (2) there is a simple hyperactivity of metabolic functions in typhoid which renders weight maintenance difficult (Benedict and Surányi,⁶ Ewing and Wolf,⁷ Grafe⁸).

Following Graves, a few clinical men attempted to nourish their typhoid fever patients better than before, but up to a few years ago, despite the advice of shrewd clinicians like F. C. Shattuck⁹ of Boston and A. G. Barrs¹⁰ of England, not many practitioners have dared to fly in the face of custom and resort to a high caloric intake. Recently, and largely through the influence of the enthusiastic studies carried on at the Bellevue Hospital, New York, by Dr. Warren Coleman¹¹ and his associates, clinicians have become more courageous, especially in hospital practice. A more liberal diet is now becoming general, though but few, perhaps, resort as yet to the high caloric values reached and advised by the more ardent advocates of liberal feeding.

METABOLISM IN TYPHOID

Laboratory workers have done and are doing their part to establish a rational basis for the feeding of fever patients. As early as 1882 von Hoesslin¹² had shown that foods were absorbed almost as well in typhoid fever as in health. A little later, a long series of publications appeared in St. Petersburg reporting the results of work in Chudnowsky's clinic. These Russian observers, according to Dubois,¹³ who gives a brief summary of their work, found that foodstuffs were very well absorbed in fevers, though the absorption was affected to a certain extent by the patient's general condition. Similar results were obtained by von Leyden and Klemperer.¹⁴ These earlier observers found that emaciation could be, to a large extent, prevented by liberal feeding in typhoid, though despite the administration of large quantities of protein they were unable to maintain nitrogen equilibrium in the disease.

In 1909 appeared the important article by Shaffer and Coleman¹⁵ on the protein metabolism in typhoid fever. Their investigations were undertaken with the idea that the destruction of body protein in fever might be reduced to normal limits by adding large quantities of carbohydrate to the food, to act as protein-sparers. Their research is a remarkable one and will doubtless be looked back to in future as an unusual example of a metabolic study of high order at a time when but relatively few such studies were being undertaken in this country. They concluded from their work that by the use of diets of high caloric value, especially rich in carbohydrates, it is possible to prevent not only the "febrile loss" of body protein-nitrogen in patients suffering from typhoid fever, but also

that due to the so-called toxic destruction of body protein. They are inclined to believe that there is a greater need for carbohydrate in fever than in health and that if the carbohydrate of the food intake be insufficient the body-protein will be drawn on to supply energy in an available form; if, on the contrary, enough carbohydrate be fed, the body protein will be protected. An interesting feature of the work of Shaffer and Coleman is the finding that from 10 to 15 gm. of nitrogen in the food ingested is sufficient to maintain nitrogen equilibrium, provided large amounts of carbohydrate be simultaneously eaten. They found that their patients could be induced to take as much as from 1,000 to 3,000 calories in the worst stages of the disease, while in convalescence an intake of from 5,000 to 8,000 calories could sometimes be reached. Later, E. F. Du Bois, working in Lusk's laboratory, studied especially the absorption of food in typhoid fever and, confirming von Hoesslin, found that typhoid patients can, throughout the disease, absorb carbohydrates and protein as well as normal persons. He asserted, too, that they can absorb very large amounts of fat, but that the percentage of absorption is somewhat lower than the normal, especially in the earlier part of the disease. During the present year, R. A. Kocher,¹⁶ working in Friedrich von Müller's clinic in Munich, has published a paper on the metabolism in fever and compared the results with those obtained on himself and on his companion (Ferguson) when engaged in active exercise. This investigator used the nitrogen minimum (Sivén), to which excretion in the urine can be reduced, as the basis of his studies. With a very low protein intake and a high carbohydrate intake, the amount of nitrogen excreted in the urine can be reduced to as little as one-third of the amount given out on total fasting. The nitrogen minimum is a high value in fever even with a caloric intake of 80 calories per kilogram. This increase in "nitrogen minimum" is due neither to increased expenditure of energy nor as Graham and Poulton have shown to the fever alone, nor to insufficient caloric intake. Kocher points out that an analysis of Shaffer and Coleman's experiments indicates that while nitrogen loss can be compensated for by a high caloric intake, there are periods in the disease when nitrogen equilibrium cannot be maintained. Kocher's findings, therefore, support the view previously expressed by von Müller that there is in fever an actual destruction of protein due to certain special influences on the protoplasm and that it is difficult or impossible to maintain protein equilibrium at certain periods of febrile disease, even on a high caloric diet.

THE HIGH CALORIC DIET

This has been described so often that its details need not be repeated here. For those who wish quickly to inform themselves regarding its content and mode of application I would recommend the perusal of the chapter dealing with it in Friedenwald and Ruhräh's textbook,¹⁷ or, especially, of the original article by W. Coleman and of that of Crohn.¹⁸

Where good milk is not available, or in the cases in which milk is not well borne, a diet such as that recommended by G. C. Rodgers,¹⁹ of Elkins, W. Va., may

be tried. In parts of the South (Florida, Georgia, etc.), physicians have told me that they have difficulty in securing good milk and that they often have to be content with foods other than milk in the treatment of typhoid fever.

The amount of food necessary to meet the needs in typhoid fever is undoubtedly large. Though Grafe asserts that the total metabolism in a fasting typhoid patient never exceeds 2,798 calories, Coleman's studies prove that to obtain nitrogen equilibrium, from 4,000 to 5,500 calories per day are necessary, that is, from 60 to 80 calories per kilogram of body-weight. The optimal protein intake seems to lie between 62 and 94 gm. in the twenty-four hours, which corresponds to 10 or 15 gm. of nitrogen per day. The carbohydrate intake is most important; when not contra-indicated for some special reason, it should make up, Coleman thinks, a half of the calories given. Fat seems to be better borne in the amphibolous period and during convalescence than in the earlier stages of the disease.

Protein may be taken in sufficient amounts as eggs and milk. Schottmüller²⁰ and other German writers give as much as 100 gm. of scraped meat per day, but in American clinics meat is rarely given, as it seems often to excite digestive disturbances and to increase renal irritation. Meat soups are also avoided, though a little broth or consommé may be given to improve the appetite and to stimulate the secretion of the gastric juice. If soup be given, it is well to add eggs and cereal to it to increase the caloric value. Eggs may be taken raw, or beaten up with milk, or as soft-boiled or coddled eggs. From four to eight eggs may often be given in the twenty-four hours.

The carbohydrate may be given partly as milk, partly as bread or toast (with butter), and partly as lactose added to the milk, cereals and orange-albumin. Coarse cereals with cellulose residue are to be avoided. Dry toast or zwiebach buttered, if thoroughly chewed by the patient, may be used without harm. Boiled rice and mashed potatoes may be given as variety. Lactose is a very important article of the diet. It is easily soluble, is not very sweet, and can be given in large amounts without the appearance of sugar in the urine.

A liberal amount of fat in the diet will send the calories up, but not all patients bear fat well, especially early in the disease. Fat may be tried in the form of cream, of butter and of yolk of egg. Coleman has been able to give as much as 200 or 250 gm. of fat per day without causing digestive disturbances. The fat content of ordinary milk is of course considerable, and milk in amounts of from 1.5 to 2 liters per day can be given to most patients without difficulty. Some patients, however, are intolerant of milk even when modified by peptonization, or by mixing with lime-water or with sodium citrate. Some patients take fermented milks very well, but the objection to them lies in the reduction of the carbohydrate content by the fermentation.

Fruit juices, to which lactose has been added, may be given, as long as there is no diarrhea, but they should be discontinued should diarrhea develop. It must be remembered, however, that patients on the high-calory diet ordinarily have from two to four stools a day.

INDIVIDUALIZATION

Now that the pendulum has swung toward a high-calory diet in typhoid, the necessity of individualization should not be lost sight of. McCrae has pointed out the dangers of overfeeding in certain cases. I am convinced that there are some patients who cannot bear the high-calory diet; indeed, in our experience at the Johns Hopkins Hospital the resident physician, Dr. Clough, has found it difficult, in the early stages of the disease, to give as large amounts as seem easily possible in the New York Clinic, and we have had some patients to whom a large number of calories could not, we have thought, be administered wisely before the beginning of convalescence. Here good clinical judgment is essential. It is often very difficult, it is true, to say whether in a given case a digestive disturbance or a tympanites is due to some article of the diet or to a high grade of intoxication. I have obtained the impression myself that the severer forms of tympanites depend less on the food intake than on toxic paresis of the wall of the intestine due to a virulent infection or a low grade of resistance. Should tympanites or other digestive disturbances begin to appear, however, it is well to modify the diet at once and especially to restrict the intake of milk and of lactose. If, on the high-calory diet, examination of the stools shows that undigested food is passing through, the diet should be reduced.

A point emphasized by Coleman, the necessity of beginning cautiously and gradually increasing the caloric value of the intake, should be kept in mind. The plan Coleman recommends is to give a pure milk diet for two days in all cases. If the patient be very ill, he may be kept, thereafter, on a fluid diet of from 1,000 calories (1 liter milk, 50 c.c. cream, 50 gm. lactose divided into eight feedings), up to 3,900 calories (1.5 liters milk, 0.5 liter cream, and a pound of lactose, divided also into eight doses) in the twenty-four hours. Soft-boiled or scrambled eggs may be added to this diet even when patients are quite sick. In mild cases, the patients may from the beginning take, in addition, buttered toast, mashed potatoes and cereals in amounts sufficient to make the total caloric intake 4,000 per day. In convalescence 5,000 or 6,000 calories per day may often be given.

The contributions of trained dietitians to the technic of administering a high-calory diet are very welcome. The attractive dishes devised by Miss Edna Cutler,²¹ formerly of Bellevue, make a good start in this direction, and it is to be hoped that the dietitians in various hospitals will gradually supply us with a whole series of appetizing dishes which may be given without harm to our typhoid patients. In this connection I have found the cook-book of Jürgensen²² a valuable aid. I wish it could be translated into English, as the caloric content of each recipe is given. In calculating the caloric content of ordinary foods the little book by Locke²³ on "Food Values" is most helpful.

CLINICAL RESULTS

The careful analysis of the patients in Bellevue Hospital showed a lower mortality among the patients fed on the high-calory diet than among the other cases. Complications (hemorrhage; perforation) and relapses

were no more frequent than in patients fed in the old way. The great gain from the liberal diet consists in the lessening of emaciation, the shortening of convalescence and the prevention of exhaustion phenomena after the disease has run its course. Most patients lose 5 or 10 pounds even on the high-calory diet, though now and then a patient can maintain his weight. In the Johns Hopkins Hospital we have been struck with the better appearance of our patients during convalescence since we have fed our patients more liberally. Since convalescence can be shortened and emaciation prevented, there is good reason to believe that post-typhoidal psychoses and post-typhoidal neurasthenic states will be less common than under the old regimen. It is a little too early yet to speak positively regarding this point, but my clinical impression thus far favors the view stated.

In order that the high-calory diet may be successfully given, the details of the nursing must be carefully worked out. The times of feeding during the day and night, the relations of the food intake to the water intake, the quantities given each time, the variety of the food given, the estimation and recording of the calories in a special chart, the regular weighing of the patient, the encouragement of the patient, the tact and judgment of the nurse, are all points to be considered.

The high-calory diet in typhoid will be objected to by many patients, by many nurses, and by many physicians. It is no wonder that prejudice against it should be deep-seated, if we recall the past history of the dietetic treatment of typhoid fever. This prejudice is contributed to by false ideas regarding the character of the intestinal contents in typhoid and their relation to the ulcers. It is contributed to by an old fallacy—the argument *post hoc, ergo propter hoc*—which ascribed hemorrhage, perforation and relapse in typhoid to dietetic errors because they sometimes followed them. There are physicians in practice to-day who still believe it almost criminal to permit a typhoid patient to eat a piece of dry toast even when it is thoroughly masticated. Perforation will occasionally occur, it is true, after a patient has eaten dry toast, but this observation is far from establishing a causal relation between the two events.

As Dr. Edsall is to deal especially in this symposium with the dietetic limitations in certain cases of typhoid fever, I shall leave this side of the subject to him to present.

In conclusion, then, the evidence is at present in favor of the liberal feeding of typhoid patients, provided always that the diet be adapted to the needs and powers of the particular patient under treatment with avoidance of anything like a rigid routine applied to all cases indiscriminately.

Johns Hopkins Hospital.

Child Psychology and Education.—Normal children are neurologically incapable of following the logical sequence of ideas as generated by the adult. Their thought is unstable and incomplete because the association fibers in the brain are only in the process of development, are only as yet parts of an unfinished machine. A knowledge of this physical fact throws a light upon the state of mind which perpetrates the schoolboy "howler." "The weight of the earth is reckoned by comparing a mass of known lead with a mass of unknown lead," may produce a smile from the "man in the street," but the student of child life sees evidence of mental strain, confusion of ideas and only a partial absorption of an education which deals with *words* instead of *things*.—John Arrowsmith, *Jour. State Med.*

THE EFFECTS OF FOOD ON METABOLISM
IN TYPHOID FEVER*

WARREN COLEMAN, M.D.

NEW YORK

After it had been ascertained that a patient could be carried through an attack of typhoid fever with the loss of but little if any weight and that the large amount of food required for this purpose is absorbed nearly as completely as in health, the next step in the investigation of the diet problem in this disease was obviously to determine the extent to which the food was utilized after its absorption and the effect it had on the general metabolism.

The investigation which forms the basis of this paper was undertaken in association with Dr. Eugene F. Du Bois.¹

There are two methods by which such an investigation may be carried out: direct or indirect calorimetry. Direct calorimetry implies the actual measurement of the heat produced by the body and requires an elaborate and costly apparatus. In indirect calorimetry the heat production may be calculated from the oxygen consumption and the carbon dioxid output, making allowance for that portion of the respiratory exchange which is due to protein metabolism.

Several types of apparatus have been devised for measuring the amount of oxygen absorbed and the amount of carbon dioxid given off during predetermined periods of observation. The apparatus which we employed and which we believe to be the most accurate is the Benedict "universal" or "unit" apparatus. A brief description of it will facilitate the discussion of the results which were obtained. The diagram is schematic. The machine consists of a closed circuit of tubes in which are interpolated a blower (*E*) to maintain an efficient circulation of air, two Williams' sulphuric acid bottles (*A* and *B*) to absorb the water-vapor of the breath, a bottle of soda lime (*S*) which takes up the carbon dioxid, a third bottle of sulphuric acid (*C*) which absorbs the water driven over from the moist soda lime, and a water-bottle (*F*) to moisten the air before its return to the respiratory passages. Fresh oxygen is admitted at *O*₂. Expansion of the circuit is provided for by means of a rubber bag (*D*) or a spirometer which rises and falls with expiration and inspiration respectively. The patient is connected with the apparatus by means of rubber tubes (1 and 2) which are inserted into his nostrils and made air-tight. The patient's mouth is sealed with adhesive plaster to prevent his opening it through inadvertence or through falling asleep.

When a patient is connected with the machine it is obvious that the only substances he can add to the air in the circuit are carbon dioxid and water; the only thing he can take from it is oxygen. The loss of weight by the oxygen-container and the gain in weight by the soda lime bottle (plus sulphuric acid bottle *C*) correspond to the amounts of oxygen absorbed and carbon dioxid given off during the period of observation. It may be added that the observations were made in periods of fifteen minutes each.

Kraus² was among the first to study the total metabolism in typhoid fever. He found that the metabolic processes do not depart essentially from the normal, and that the respiratory quotient in the postabsorptive (*nüchtern*, fasting) state corresponds to the nutritive condition of the body at the time of the observation, that is, to the completeness with which the storehouses have been filled. Following Kraus came a number of investigators (Regnard, Riethus, Rolly and Meltzer and others³) who, though working with different types of apparatus, obtained respiratory quotients which were so low that it was necessary to assume the occurrence of abnormal processes of metabolism in fever to explain them. This lack of confirmation cast doubt for a time on Kraus' conclusions, but the work of the last few years (Grafe⁴, Rolly⁵) is in agreement with that of Kraus, and the conclusion appears to be inescapable that the abnormally low quotients were due to some undiscovered error of technic.

Our studies of the total metabolism in typhoid fever were begun in the fall of 1911 and have been continued through each succeeding typhoid season.⁶

Since the investigation was undertaken primarily to determine whether the high-calory diet exerted any deleterious influence on the patient and whether and in what manner the food was utilized after its absorption, practically all of the observations were made shortly after a meal, on patients who had been receiving large amounts of food. This fact should be borne in mind in comparing the results with those of previous investigators whose patients had been without food for from six to fourteen hours.

HEAT PRODUCTION

The total metabolism, or heat production, was calculated from the oxygen consumption and the respiratory quotient, since the caloric value of the oxygen varies with the height of the quotient. Heat production is expressed in terms of calories per kilogram per day or per square meter of body surface per hour or day. The latter method is the more accurate but is less practical for routine clinical work.

Febrile Period:—The heat production of the high-calory cases (fifty-five observations), averaged for the entire febrile period, was 35.9 calories per kilogram per day.

The heat production in the postabsorptive state (fifty-one observations by other investigators), likewise averaged for the entire febrile period, was 35.3 calories per kilogram per day.

In both groups of cases there is an increase in heat production (35.4 per cent. and 33.2 per cent. respectively) above the average (26.5 calories per kilogram per day) of seventeen normal persons for the most part collected from the literature to serve as controls. But the increase in the high-calory cases over those in the postabsorptive state is only 1.7 per cent, and lies within the limits of error.

It is evident, therefore, that even large amounts of food (at least, when the protein is kept relatively low) do not increase the heat production, or the fever, in the febrile stage of typhoid.

In health the taking of food is followed by an increase in heat production which, according to

1. The detailed results of the investigation will appear shortly in the *Archives of Internal Medicine*.

6. During the season of 1913-14 the calorimeter, constructed in the Second Medical Division of Bellevue Hospital under the auspices of the Russell Sage Institute of Pathology, was employed. The results obtained with its aid will form a separate communication.

Rubner, is due to its specific dynamic action, and it has simply been assumed that food exerts such action in fever. Many years ago von Hoesslin estimated the supposed increase in metabolism at 10 per cent. to 15 per cent. and later writers accepted his estimate.

The reason food does not exhibit its specific dynamic action in typhoid fever can, at the present time, only be conjectured. It is not without analogy, however, for in health the specific dynamic action of food does not appear when metabolism is stimulated by external cold.

Convalescence.—The heat production of the high-calory cases was essentially uniform in the first four weeks of convalescence. The average of forty-nine observations covering these weeks was 36.2 calories per kilogram per day. This is 36.6 per cent. above normal and slightly less than 1 per cent. above the heat production in the febrile period.

The reason for the persistence of such a high metabolism into convalescence has not been definitely ascertained. Since the temperature remains normal and the patients show steady improvement in weight and strength and appearance, however, there is no present reason to consider that the high metabolism contra-indicates the liberal use of food.

In the postabsorptive state, in the case of patients who have received insufficient food during the fever, the metabolism increases with each week of convalescence, at least up to the fourth, as is shown in the following averages: In the first week the average of 25 observations was 26.9 calories per kilogram per day; in the second week, the average of 18 observations was 28.3 calories; in the third week the average of 15 observations was 29.7 calories; in the fourth week the average of 24 observations was 30.6 calories.

Since, under the older methods of dieting, the total food is gradually increased as convalescence progresses, the increasing metabolism may be considered to represent the specific dynamic action of the food.

THE RESPIRATORY QUOTIENT

The relation of the carbon dioxide output to the oxygen consumption constitutes the respiratory quotient, $\frac{\text{CO}_2}{\text{O}_2}$, which, together with the nitrogen of the urine, furnishes information respecting the nature and amounts of the substances which the body is consuming.

The chemical composition of carbohydrate is such that when it is completely oxidized to carbon dioxide and water, either within or outside of the body, the volume of carbon dioxide produced and of oxygen consumed are exactly equal; consequently, the quotient is 1.0. When fat alone is completely oxidized to carbon dioxide and water, the quotient is 0.7. When protein alone is oxidized to urea, the form in which the greater portion of it leaves the body, the quotient is 0.8.

But the body in its metabolic activities always utilizes more than a single foodstuff and the value of the respiratory quotient varies according to the proportions of protein, fat and carbohydrate consumed; the greater the proportion of carbohydrate, the higher the quotient. Quotients over 1.0 are obtained during the transformation of carbohydrate, an oxygen-rich body, to fat, which is oxygen-poor. According to current belief, the respiratory quotient never falls below 0.72 in fever.

Febrile Period.—In the febrile period the average respiratory quotients of the high-calory cases rose

steadily from 0.83 in the earlier stages to 0.88 in the later. The average quotient for the whole period was 0.86.

The average respiratory quotients of the postabsorptive cases exhibited a tendency to fall. Though the fall is slight it suggests the gradual depletion of the glycogen reservoirs in consequence of the insufficient food-supply. The average quotient for the whole febrile period was 0.767.

This difference of nearly 10 points in the average respiratory quotients of patients after food and in the postabsorptive state is very significant. Since the height of the quotient corresponds to the relative proportion of carbohydrate consumed, the higher quotient of the high-calory cases clearly indicates that the body utilizes carbohydrate when it is available in preference

Diagram of the Benedict "universal" or "unit" apparatus for measuring absorption of oxygen and output of carbon dioxide.

to fat or protein for the increased production of energy in fever just as it does in health when called upon to perform extra work.

Convalescence.—In the first week of convalescence the average respiratory quotient after food was 0.93. In the second week the average had risen to 1.01, indicating that, in some cases, the formation of fat from carbohydrate was in progress. In the third and fourth weeks the quotient fell, the averages being 0.95 and 0.91 respectively.

In the postabsorptive cases the respiratory quotient rose steadily during the first four weeks of convalescence, the averages being 0.82, 0.84, 0.92 and 0.96. The rise corresponds to the increase in the food as convalescence progresses.

Though the formation of fat was observed in a few patients in the earlier weeks (in the first in two of Grafe's and one of Rolly's) the respiratory quotient

indicates that the food was still insufficient to meet the ordinary demands of the body for energy, and, at the same time, to permit the replenishment of the stores of fat and glycogen until the fourth week had been reached or even later.

GENERAL CONSIDERATIONS

We may apply the facts which this study has brought out, together with others previously ascertained, to the dietetic requirements of the typhoid patient in the following manner:

The increase in total metabolism which occurs in typhoid fever creates a demand for more food than would be necessary to maintain the same individual in equilibrium in health, if he were confined to bed. The average increase during the course of the fever reaches about 34 per cent., but, for reasons which are not yet apparent, an amount of food which is just sufficient to cover the heat production will not protect the body protein. It has been pointed out on other occasions that a much greater quantity of food is necessary for this purpose, and that the quantity varies with different patients. Rolland⁷ succeeded in establishing nitrogen equilibrium with 45.5 calories per kilogram per day, but Shaffer and Coleman⁸ were unable to accomplish it in any patient with less than 58 calories; in one patient 85 calories⁹ were required, and in others even this quantity of food did not suffice for the purpose.

It will scarcely be denied that a typhoid patient should receive in his food enough energy to cover his heat production. This amounts on the average to 35.9 calories per kilogram per day when the patient lies at complete rest, quietly breathing into the respiration apparatus. Under ordinary conditions, however, he moves about the bed more or less and thereby increases his metabolism at least 10 per cent. Therefore, on the basis of heat production alone, the food should furnish 39.5 calories per kilogram per day.

But since such an amount of food will not maintain the patient in nitrogen equilibrium, these questions present themselves: Shall the typhoid diet be arranged merely to cover the heat production, or shall the attempt be made, by giving more food, to protect the body protein? The results of this particular investigation do not furnish the answer; it must be drawn from other sources.

The production of energy is not the sole purpose of food. Food must maintain the body in a condition of equilibrium or illness, if not death, will follow.

While it is true that countless numbers of typhoid patients have survived the loss of large amounts of body protein, drawn, for the most part, from their muscles, may it not be equally true that many have died because the loss was not prevented? A normal man who is losing protein nitrogen is not receiving sufficient food. Such persons are notoriously less able than those in perfect health to resist invasion by pathogenic bacteria, or successfully to combat disease. A typhoid patient who is losing nitrogen is consuming his own tissues to supply the deficit in his food. And since it has been found possible to prevent this drain I am firmly of the opinion that the patient's best interests are conserved by giving sufficient food for the purpose, providing in all instances that the digestive

organs are capable of handling it. The patients who have come under my observation have been in better condition, the more nearly nitrogen equilibrium has been approached, and they have lost weight until this condition has been reached.

In this connection it may be recalled that a normal man cannot be maintained in nitrogen equilibrium if he receives only sufficient food to cover his basal heat production. This is due to the specific dynamic action of the food, or, as Lusk has shown, to the stimulation of metabolism by the excess of metabolites in the circulation. The reason that a typhoid patient cannot be maintained in nitrogen equilibrium on an amount of food which just covers his heat production has not yet been discovered.

The high quotients of the high-calory cases during the course of the fever have a practical relation to the selection of foods for the typhoid patient. As already pointed out, the height of the quotient is proportional to the amount of carbohydrate which is consumed. In our observations the quotient invariably rose after a meal containing carbohydrate. In one patient, a boy of 17 years, it rose on the fourth day of a relapse to 1.04 while the temperature was 102 F. The explanation of this is that the glycogen stores had been replenished during the preceding afebrile period, the food which the boy had received before breathing into the machine contained more carbohydrate than he needed for his energy exchanges, and a portion of it was transformed into fat.

This observation possesses very great interest in that it illustrates that the constructive processes of metabolism may be called into play even in the presence of fever. No reason is apparent why, if sufficient carbohydrate is supplied during the original fever, the same transformation might not occur. When a patient comes under treatment early in the disease the desirability of attempting to add to his store of fat may well be questioned. When, however, a patient has lost much weight I believe that the attempt should be made to bring the constructive processes into action even though fever is present.

The foregoing discussion should not be construed as the expression of an opinion prejudicial to the value of fat. The rôle of fat in the fever diet has not yet been completely learned. Observations designed to test its value are already under way and others have been planned. At present I am in position to say only, on the basis of clinical experience, that I believe fat to be an important constituent of the diet. In the case of patients who cannot take much carbohydrate it serves to keep up the energy value of the food and, so far as clinical observation tells, to maintain the patients' nutrition. In other patients it appears to be a physiologically economical way of increasing the total food intake.

These opinions derive support from the fact that the more intimately the processes of metabolism in fever are understood, the more nearly are they seen to approach normal. With the exception of the unexplained need of the typhoid patient for an excess of food over his heat production in order to maintain nitrogen equilibrium, the only difference, which may be considered to have been clearly established between the metabolic processes in fever and in health, is a difference in intensity.

CONCLUSIONS

1. Food does not increase the heat production or the temperature in typhoid fever, even when given in

7. Rolland: *Deutsch. Arch. f. klin. Med.*, 1912, cvii, 440.

8. Shaffer, P. A., and Coleman, W.: *Protein Metabolism in Typhoid Fever*, *Arch. Int. Med.*, December, 1909, p. 538.

9. In some of these cases the carbohydrate calories alone, in the food, reached 50 and more a day.

large amounts (at least, when the quantity of protein is kept relatively low). Therefore, the fear which has been entertained by physicians for so many years that a liberal diet would raise the temperature of the patient is proved to be groundless.

2. The body utilizes carbohydrate in preference to fat or protein to meet the increased demand for energy in typhoid fever just as it does in health when called on to perform additional work. Consequently, carbohydrate should occupy a prominent place in the diet.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. BARKER AND COLEMAN

DR. LAWRENCE LITCHFIELD, Pittsburgh: I do not think enough stress has been laid on the way in which the high-calory feeding should be instituted, the time it should be commenced, and its gradual development. In the early stages of the fever when the patient is first stricken, with coated tongue, anorexia, etc., food is distasteful and it is almost impossible to get patients to take it, but if their digestive apparatus is treated with respect during the first stage, it is not long before the patient will begin to have an appetite and a cleaner tongue. Then is the time to begin feeding, and the amount should be increased gradually with the patient's increasing ability to take care of it. Milk in typhoid fever is regarded as a liquid food, while in reality it is sometimes the most solid food we could give. There is nothing more resistant than the curds sometimes found in typhoid stools. Another danger of the milk in cities where it is usually pasteurized is that the lactic-acid bacillus is killed, but the more dangerous spores are not killed and the milk may become very toxic with the warning sourness. Some years ago we had in Pittsburgh the most beautiful place to study typhoid fever and just before taking up the more liberal feeding of typhoid patients, I had two hundred patients on fermented milk which I fortified by the addition of cream and sugar of milk, with excellent results. Milk that is fermented does not form the large curds in the stomach, and except in rare cases it is easily borne by the patient and readily taken. I gradually increased the liberality of my diet and in 1908 or 1909 was giving toast, scraped meat, eggs, etc. The patient should be given things on which he can chew. Mastication helps to keep the mouth and tongue clean and stimulates appetite and digestion. With patients who do not take food readily, when we are at a loss to introduce a sufficient number of calories, I have, in some cases, been pleased with the results of glucose solutions given by enteroclysis. In desperate cases I give dextrose in isotonic solutions intravenously, as much as 2 liters of a 5.1 per cent. solution in twenty-four hours. When constipation is troublesome the feeding of fruit and vegetables is often not advisable, and in such cases I have found paraffin oil very satisfactory. I once had 150 consecutive cases of typhoid fever on small daily doses of Epsom salt. There were no accidents and no unusual percentage of sequelae and the mortality was lower or a little less than my average. I think, however, paraffin oil is better than Epsom salt for troublesome constipation in typhoid fever. My last patient was a young married woman, six months pregnant, with paratyphoid infection complicated by an acute hepatitis and cholecystitis. She was very sick, but, after the first few days, took a liberal diet and made an uneventful recovery.

DR. O. T. OSBORNE, New Haven, Conn.: Tympanites, which I believe is not a symptom, but a complication, is most important. It means a disturbed digestion, with fermentation, and it interferes with breathing, with the action of the heart, and vastly increases the danger of hemorrhage and perforation. Hence, tympanites should be prevented, if possible, and the diet and care of the bowels is all-important. Inflammation in the intestines in typhoid fever is a surgical

process, and the cleaner the small intestine is, the better for the patient. I would not allow constipation or a diarrhea, except what may be termed a therapeutic diarrhea; namely, the bowels should be moved at the will or decision of the physician. I give calomel or castor-oil in the beginning of the disease, and every alternate day the bowels are moved by cascara, aloin, or a saline. On the intermediate day the nurse gives a rectal injection of 1 ounce each of glycerin and water. After the bowels have moved once thoroughly, or at most twice, I direct the nurse to give a tablet of morphin $\frac{1}{10}$ grain. This will stop excessive action of the bowels and check peristalsis. The patient should have all the nutriment necessary to carry on all of his metabolism: I give a cup of coffee in the morning, with a little sugar in it; two cups of oatmeal gruel a day; and two whole eggs a day, either raw or poached. Raw egg-albumin, or egg-white, is not a satisfactory nutriment. If the patient is well enough to chew, he should have dry or buttered toast. He should also have, daily, the juice expressed from a pound of chopped beef which has been first covered with cold water, allowed to stand an hour, and then the whole juice and water expressed out. This amount of nutritive liquid may be served salted at two or three feedings. The patient should also have a pint of milk a day, the juice of one orange, and two or three tablespoonfuls of lime-water. If the tongue is much coated, the patient should have a little dilute hydrochloric acid after milk, eggs, or meat. If it is best not to administer meats or meat-juices, the patient should receive a small dose of iron each day, and my choice is *Eisenzucker*. In spite of such care of the diet and the bowels, some tympanites develops, I use yeast or lactic-acid bacilli treatment.

DR. ALLAN C. EUSTIS, New Orleans: My experience was acquired in a large country practice after having had the disease itself. I had so much milk poured into me that I became nauseated at the sight of it, and about the tenth day I wanted carbohydrates in the form of toast and molasses, etc. In my practice in the country I began to feed my patients, more especially on carbohydrates, when Dr. Coleman's work came out. I have since been an ardent advocate of his principles. I think we make the mistake of paying too much attention to quantity and not enough to quality. I believe tympanites is not a symptom but a complication, and, further, that the dry, coated tongue is also a complication, and can be cleared up by the proper dietetic measures. In the last three years I have collected twelve cases in which we have kept the patient's tongue dry and clean, simply by a properly selected diet. Analyses of the gas passed by the rectum in several cases have shown carbon dioxide as rare, hydrogen sulphid and methane predominating. I do not believe, therefore, that carbohydrates cause tympanites, but consider protein putrefaction as responsible. A high indican test is an indication to take the patient off of protein and substitute carbohydrate in any easily digestible form, such as sugar, toast, mush, cream of asparagus, soup, gruels, etc. A patient should be given three meals a day and should be treated the same as a healthy person, allowing ample time at night for sleep. In this way you do not tire out the gastric juice, and the caloric content can be kept up by giving fruit juices with sugar of milk between meals. I have often allowed patients to take a cocktail before their meals if they have been used to it. Frequent examinations of the twenty-four-hour nitrogen output of these cases showed that they do well with 5 to 10 gm. of nitrogen per day. Intestinal poisons must always be considered when treating a typhoid patient, and I would recommend the daily examination of the urine for indican, which, when present, should be eliminated by a lowering in the protein of animal origin.

DR. LEWELLYS F. BARKER, Baltimore: The three striking changes, clinically, in the appearance of typhoid patients in hospitals are (1) the changes in the tongue; (2) the lessening of the tympanites, and (3) the prevention of extreme emaciation. We do not see the old "typhoid tongue" any more. We rarely see marked tympanites, with careful feeding; occasionally, however, we do see it. I hope some one will find out how always to prevent tympanites. Only last week, a close friend of mine died from typhoid with tympanites and per-

foration, temperature 106. If we could have prevented the tympanites in this case he might have lived, but I think he had toxic paralysis of the walls of the intestine. I think bacteriologic study throws some light on relapses. In the first week of the disease, there are always large numbers of typhoid bacilli in the blood; there are relatively few in the second and third week. There is a new bacillemia with every relapse. We clinicians feel that a great debt of gratitude is due to the men who carry out the careful metabolic studies on which improvements in therapy can be based. The final judgment has, however, to be made by the clinical men who apply these studies in the actual treatment of a large series of cases. The laboratory research must be followed and supplemented by clinical research—the testing by actual observations, at the bedside, of the applied findings.

DR. WARREN COLEMAN, New York: Few points remain to be considered. The first concerns the remark of Dr. Barker concerning the possible objections to the use of the high-calory diet. He suggested that some nurses complain of the amount of work which the diet entailed. Without exception, the nurses to whom I have spoken of the matter have agreed that the preparation of the food was less troublesome than the care of patients under the older methods of dieting. The high-calory patients are rarely delirious and they rarely suffer from diarrhea, whereas, formerly these symptoms were common and often demanded a nurse's whole attention. The objection to fermented milks is that their fuel value has been reduced by the removal of the milk-sugar. With a diet in which proteins predominate the putrefactive organisms dominate the flora of the intestine. In the presence of large amounts of carbohydrate the fermentative type predominates. This is an additional reason for keeping the protein low—from 10 to 15 gm. of nitrogen in twenty-four hours. I believe that in most cases tympanites is due to injudicious dieting. I never give laxatives or purgatives in typhoid. A simple enema every morning empties the lower part of the intestine and answers every purpose.

THE PSYCHOSIS OCCURRING DURING THE COURSE OF PERNICIOUS ANEMIA

G. H. WILLIAMS, M.D.

First Assistant Physician, Columbus State Hospital
COLUMBUS, OHIO

In reporting the two following cases I wish to call attention to the abnormal *mental* condition occurring during the course of pernicious anemia, not coming especially as one of the final complications of the disease. It is perhaps of little moment to see such a condition occurring as one of the late complications, but we infrequently read in the literature of a well-defined psychosis making its appearance weeks and months previous to the death of the individual.

CASE REPORTS

CASE 1. (No. 8043).—Male, white, aged 52, farmer. Admitted to the Columbus State Hospital Dec. 24, 1912. Commitment papers state that the "onset has been gradual, that he is suffering from pernicious anemia with peripheral neuritis, is at times excited and dangerous, threatening to kill different members of the family. Has hallucinations and thinks that different persons were trying to kill him. Is insanely jealous of his wife; at times having violent, mad fits." When admitted to the hospital the patient appeared intensely sick and was unable to walk without assistance, having marked dyspnea on the slightest exertion. He was at once placed in bed and the initial examination showed him to be a man of quite marked intelligence, possessing quite a little insight into his present condition, oriented as to location and apparently well satisfied. He realized that he was quite sick physically and desired to do all that he could to improve his condition. From his history we learn that he has been quite a prosperous man and for many years his married life was happy.

Finally, of his own accord and for no real cause he separated from his first wife. He soon married, but his second union had been unhappy. For the past few weeks he had been very suspicious of his second wife, thinking that she was trying to poison him, or in some other way cause his death. He gave as his reason for such belief that his second wife had always been jealous of his first one. He also stated that because he had quite an estate his second wife was anxious that he die so that she would fall heir to his property. At different times during the examination he would close his statement with the remark that "although this seemed very real to him it must certainly be imaginary." He showed very little difficulty in speech, pronouncing test phrases quite well. There were never any convulsive attacks, blind or dizzy spells, and he claimed that he had never had any defect of memory.

In about three weeks after the first examination the patient showed some marked changes both physically and mentally. He was well oriented as to place but could not remember how long he had been in the hospital. At this time there was also some indecision in his own mind as to whether or not he had had any real mental trouble. He could see no reason why he should have been brought to the hospital. He grew very toxic at intervals, so that he was confused and disoriented in every field. When aroused from his lethargy he recognized those about him, but when left alone, soon relapsed into a semi-conscious condition. The functions of the arms and legs became less and less efficient and for two or three weeks previous to his death he was almost entirely helpless. He died March 17, 1913, three months after admission. When admitted physical examination was as follows:

Physical Examination on Admission.—Patient is 5 feet 5 inches in height, weight 131 pounds, light hair, blue eyes, pupils dilated equally, tongue clean, dark red in color; skin is clean, somewhat tinted with yellow, musculature very flabby, breath has bad odor, inguinal and postcervical glands enlarged, liver dulness increased downward. Examination of chest negative. Nervous system: right patellar tendon more active than the left, marked ankle-clonus of the right side. Romberg's sign present. Gait unsteady. At the time of admission to the hospital blood examination was practically negative, but from an examination made Oct. 15, 1912, by Dr. Frank Winders we learn that the hemoglobin was 40, red blood-cells 1,750,000, whites 5,200. Differential count—polynuclears 48, small mononuclears 40, large mononuclears 7, eosinophils 2, megaloblasts 3, normoblasts 4, 100 whites; color index plus; polychromatophilia, poikilocytosis. At the time of this examination patient was of a pure lemon tinge, there was marked throbbing of the muscles of the neck, severe dyspnea, palpitation of the heart and digestive disturbances. The heart was dilated. A loud systolic murmur was heard all over the cardiac region and transmitted to the large vessels of the neck. Blood-pressure 105. Pupils sluggish, no patellar reflexes present and there was some unsteadiness of the limbs and feet. The diagnosis was pernicious anemia with very unfavorable prognosis; in fact, the patient was not expected to live more than three or four weeks. It was possible to obtain consent for only a partial necropsy.

Necropsy.—All the fatty tissue showed the characteristic lemon color. The left kidney was malformed, showing some old scars or contractures. The spleen was enlarged and intensely congested—a large splenic tumor. Liver was enlarged, markedly congested. Gall-bladder distended with bile, but no stones. Lungs on each side contained air but were bound down by adhesions. The heart was smaller than normal and full of clot; pericardium very yellow. The intercostal as well as the other muscles examined were of a deeper red color than normal. The brain and spinal cord were not examined. Other organs were opened *in situ* and replaced. From the gross examination the diagnosis of pernicious anemia was made.

CASE 2 (No. 8206).—Male, white, aged 55, farmer; committed to the Columbus State Hospital June 14, 1913. The commitment papers stated that he was excited, had delusions concerning his previous medical treatment and also at times had delusions of persecution and of accusation. He, at

times, manifested quite marked mental disturbances. According to the statements of the committing physicians he was thought to have advanced pulmonary tuberculosis.

When admitted to the hospital the patient was quiet and well behaved. He was placed in bed and given the usual routine treatment and the preliminary examination revealed the following mental state:

Preliminary Examination.—"The patient is unable to tell where he is, the day, the month, or the year, and concludes his answers with 'I have been doped up so much that my ears ring.' He confuses his present location with the place—county infirmary—where he had been an inmate several weeks previously. He insists that he has had no trouble with his mind and that the immense amount of medicine he has taken is responsible in every way for any peculiar symptoms he may manifest. Although he complains of some roaring in his head he has no clear-cut hallucinations. His memory shows lack of accuracy for both recent and remote events and his general mood is much happier than his physical condition would warrant."

Examination.—A month after his admission he still showed temporal, spatial and personal disorientation. During a conversation he disclosed delusions of persecution, hallucinations of sound and illusions, and during the entire examination there was failing attention and lack of appreciation of his condition. He was much reduced physically and the skin showed a well pronounced lemon yellow tint. Aside from some slight paresthesias the nervous system was negative. The blood examination at this time showed a marked pernicious anemia.

During the last two or three weeks of his illness he manifested marked signs of cerebral anemia, the roaring in his head becoming much more severe, vertigo was constant and unless assisted he was not able to walk. His sensibilities were diminished and he gradually grew so clouded that he could not converse with those about him. Death occurred Aug. 4, 1913, about seven weeks after admission. There was no necropsy.

DISCUSSION

When we attempt to classify these two cases we find no definite group in which to place them, unless it should be with the intoxication psychoses. To summarize, we have two individuals with well defined pernicious anemia, showing in common many mental signs, namely, lack of orientation—in the one case in every field and in the other especially in regard to place; lack of insight; such delusions as we commonly meet in paranoid states—those of a persecutory type; the memory in one case apparently normal, until late in the condition, while in the other there was lack of accuracy for both recent and remote events; the mood in both parties much happier than the physical condition would warrant; lack of attention and appreciation, and numerous physical signs such as paresthesias, diminished sensibilities, vertigo, speech disturbances, loss of functions of the arms and legs, ankle-clonus, unequal patellar reflexes, Romberg signs, unsteady gait. Apart from the abnormal mental conditions present it is evident that we are dealing with some lesions of the brain and spinal cord, such as have been described by various writers in their reports of cases.

Hereditary Development and Differentiation.—Hereditry may be defined as the particular germinal organization which is transmitted from one generation to the next. Inheritance or heritage is the sum of all those qualities which are determined or caused by this germinal organization, by which it is transformed into the adult organization. Differentiation is the formation and localization of many different kinds of substances out of the germinal substances, of many different structures and functions out of the relatively simple structures and functions of the oosperm.—Edwin Grant Conklin, *Pop. Sc. Month.*

THE BACTERIOLOGY OF TYPHUS FEVER *

RUSSELL M. WILDER, M.D.

CHICAGO

The relatively recent experiments of Nicolle,¹ Ricketts and Wilder,² Anderson and Goldberger,³ revealing the manner in which typhus fever was borne from patient to patient by lice, and the later investigations of Anderson and Goldberger³ proving the identity of Brill's disease with typhus fever, have aroused new interest in this disease and the next step toward the solution of its etiology, the discovery of the specific germ, is awaited expectantly.

The bacteriology of typhus has been studied for years and numerous investigators have reported the discovery of organisms in typhus blood. No one of them, however, has thus far been able to establish the specificity of any particular organism. In general the students of the disease may be grouped into two camps, the one championing a protozoan etiology, the other maintaining that typhus is caused by a bacterium.

Among the first important investigations were those of Hlava⁴ (1888), who grew a streptobacillus from the blood and spleen of twenty of thirty-three patients, but who considered more important a protozoan which he later (1892) advanced as the cause of typhus. Thoinot and Calmette⁵ in 1891 found small, actively motile threads, flagellates, which disappeared from the blood in twenty-four hours, and Gotschlich⁶ described minutely an intracorpuseular protozoan which he classified as "pyroplasma bigeminum." Dreyer,⁷ Kireef⁸ and others were unable to confirm these observations. More recently Krompecker, Goldzieher and Augyan⁹ obtained a variety of different organisms from the blood, streptococci, and staphylococci, Friedländer's bacillus and others, but considered more important than these bacteria certain structures resembling malarial plasmodia which they found both within the blood corpuscles and free in the plasma; oval, pear-shaped and rod-like bodies taking an intense blue stain with Giemsa. Very recently Hegler and von Prowazek¹⁰ have described minute bodies filling many of the leukocytes and found also free in the plasma, taking a deep red stain with Giemsa considered to be stronglyloplasma. They were found both in patients and in infected apes, but not constantly.

The discovery that typhus is an insect-borne disease lent strength to the protozoan theory of its etiology because of analogy with such insect-borne infections as malaria, sleeping-sickness and relapsing fever. It is only more recently that instances of insect-borne bacterial diseases have come to light, but a consideration of these, of plague transmitted by the flea and rocky mountain spotted fever by the wood ticks, should warn against drawing too hasty conclusions about typhus.

Bacteria of all kinds have been described in the blood of typhus patients. Following Hlava came Lewaschew¹¹ in 1892 with cultures of micrococci and Dubief and Brühl¹² with delicate diplococci which were cultivated on the usual laboratory media. Balfour and Porter¹³ in 1899 described a diplococcus. Deserving of greater consideration, however, are the more recent investigations of Galesesco and Slatineano¹⁴ (1906), Klodnitsky¹⁵ (1907), Rabinowitsch¹⁶ (1908), Ricketts and Wilder² (1910), McCambell¹⁷ (1910), Predjet-schensky¹⁸ (1910), Fürth¹⁹ (1912) and Plotz²⁰ in 1914. All of these authors describe bacilli the descriptions of which bear a certain resemblance.

Galesesco and Slatineano¹⁴ observed in fresh preparations of blood, elements 2 to 3 microns in length with refractile poles, non-motile, polar-staining. These observations were not constant. The same authors also described a large number of other bacteria.

Klodnitsky¹⁵ in 1907 found thin bacilli in laked blood. In 1908 he obtained a culture of bacteria which proved highly virulent for mice. Artz and Kerl²¹ were unable to confirm this observation.

Rabinowitsch¹⁶ observed in the peripheral blood diplococci and rods which by Giemsa stain show a lighter middle zone. The cultures contained Gram-positive diplobacilli. In the first generation these were agglutinable by typhus serum, but not later, which is explained by Rabinowitsch in a subsequent paper by the sticky character of the colonies and the difficulty in making homogeneous suspensions. The cultures were pathogenic for guinea-pigs and rabbits, producing a disease much like typhus in man. Later, in 1912, Rabinowitsch obtained inconstantly a complement deviation, using an extract of culture as antigen. Cultures older than two months proved unavailable. The patient's serum (antibody) had to be taken not earlier than the sixth day of convalescence.

In December 1909 an investigation of typhus fever in Mexico City was undertaken by Ricketts and

myself.² Blood serum of typhus fever patients was found to be sterilized by filtration through Berkefeld filters, an observation which was subsequently confirmed by others, and it was the encouragement offered by the results of these experiments that prompted the careful attention which we then bestowed on the microscopic examination of the blood of typhus patients and the organs of infected lice. If the organisms were large enough to be held back by the filter, they should be visible with the powers of the microscope. By these investigations we obtained results which were reported in April, 1910, as follows:

1. In the stained (Giemsa) preparation of the blood of patients, taken on from the seventh to the twelfth day of the disease, we invariably have found a short bacillus which has roughly the morphology of those which belong to the "hemorrhagic septicemia group." Usually it appears to stain solidly, but on minute examination an unstained or faintly stained bar is seen to extend across the middle. Occasionally two organisms are seen end to end. Exact measurements have not been made, but when compared with the size of the erythrocyte, their length is estimated at hardly more than two micromillimeters, and their diameter at about one-third of this figure. Certain other bodies, the identity of which is not so clear, may represent degeneration or involution forms of the above. They consist of two stained granules, connected by an "intermediate substance," which is stained faintly blue or not at all. Frequently one of these granules, or "poles," is larger than the other and stained a deep purple, whereas the smaller takes a faint blue color.

2. In moist preparations of the blood of patients, bacillary bodies, with a structure like that mentioned above, have been encountered in all cases. The differentiation of the forms into two halves, separated by a line or narrow zone of a substance of different refractive power, may be observed. They possess no active motility, but vibrate more or less rapidly.

3. The dejecta and various organs of a large series of lice have been stained in a similar way and examined for the presence of micro-organisms. Certain groups have been deliberately infected by permitting the lice to feed on patients, while others were supposedly normal, having been collected from healthy individuals. Streptococci, staphylococci, an oval bacillus occurring in clusters, and certain solid-staining bacilli are encountered irregularly and indifferently in the feces and intestinal contents of both "normal" and "infected" lice. Polar-staining organisms have been found occasionally in the feces and intestinal content of "normal" lice, whereas they are present almost constantly, and often in large numbers, in similar material from "infected" individuals.

Protozoa have not been recognized.

These observations were reached quite independently, as Rabinowitsch's publication in 1908 had not come to our attention and the more extensive reports appeared later.

During these earlier investigations I tried to obtain further proof of the specificity of our organism by making an emulsion of the organisms of infected lice in which the bacilli were numerous and attempting agglutination with serum from convalescent patients. These experiments were not reported, as they involved a rather difficult interpretation, the emulsions containing many contaminating bacteria. I felt, however, fairly convinced that the bipolar bacilli were agglutinated; the preparations with typhus serum differed markedly from the controls with normal serum.

Our investigations included the study of some thirty infected monkeys and a hundred or more patients and in every case blood cultures were made. As mediums agar and large flasks of broth were used and no cul-

tures were diagnosed before a week of incubation; in only two instances did any of the flasks contain any growth and these were obviously contaminations. The cultures were made as a control of our work on transmission, but the results are independently important in that they show the difficulty in the cultivation of the typhus bacteria. To my mind they cast some doubt on the results of those experimenters who have reported the cultivation of bacteria on these ordinary media.

Our observation of bipolar organisms in the blood was later confirmed by Gavino and Girard,²² by Nicolle² and by Hegler and von Prowazek.¹⁰ I²³ have since reexamined the blood preparations made during our earlier study and feel quite certain that our findings are as significant as we then thought them to be. In reply to the criticism of Nicolle and others that these organisms are present in the blood in too small numbers to be accepted as the cause of the disease, I would call attention to the scarcity of bacilli in the blood of typhoid patients (*Typhus abdominalis*) and the difficulty in finding diplococci in the blood of pneumonics.

Following the publication of our observations appeared researches by Wilson²⁴ who cultivated a diplococcus in fifteen of thirty-three cases, and the investigations of McCambell¹⁷ who observed organisms in the blood which gave the impression of being diplococci, but on closer study were shown to be bacilli with polar staining. McCambell made cultures on a variety of media, but all were negative.

In 1910 also appeared the publications of Predjetschensky¹⁸ who observed in blood, urine and sputum an organism, usually rod-like, at times a diplobacillus, Gram-negative, non-motile, polar-staining. Cultures were positive in 100 cases when made between the sixth and ninth day of the disease, 2 to 5 c.c. of blood being implanted in 200 c.c. of broth, growth visible after twenty-four or forty-eight hours. The organism proved pathogenic for mice and guinea-pigs, was agglutinated by typhus serum but only in strong dilutions, 1:10 in one hour and 1:40 in four hours. Other immunologic tests are not reported, nor is there any proof that the animals for which the germs proved toxic had developed actual typhus fever.

Silberberg²⁵ in 1912 found in the cerebrospinal fluid a micrococcus which showed a clear middle zone, and Fürth¹⁹ in 1912 described in the blood a short, thick bacillus with a clear central zone which proved cultivable in 38 per cent. of cases. The growth was difficult and polymorphous tendencies were exhibited on artificial media. Agglutination with typhus serum was indefinite and only a slight pathogenicity was found for apes, guinea-pigs and rats.

In 1913 Müller obtained cultures of a diplobacillus in five of eleven cases of typhus. The organism was Gram-positive at first, subcultures Gram-negative, slightly toxic for mice but non-toxic for macacus monkeys. He believes it the same organism as that described by Fürth, Rabinowitsch and Predjetschensky.

Finally and to my mind most encouraging, is the recent report of Plotz.²⁰ Plotz made anaerobic cultures

of typhus blood, which in my opinion was a wise procedure, and, although his methods are not described in the preliminary report, he seems to have succeeded in obtaining eleven positive cultures in twelve cases of typhus fever, six of these being the milder Brill's disease. The cultures when injected into guinea-pigs produced a febrile reaction similar to that which occurs after inoculation of typhus blood. Complement deviation was obtained in six of eight cases, using an antigen made from the bacillus and serum from patients after crisis. The morphologic description is as follows:

The organism is a small Gram-positive pleomorphic bacillus from 0.9 to 1.93 microns in length, the breadth being from one-fifth to three-fifths the length. It is non acid-fast, has no capsule or polar bodies and can be demonstrated with appropriate methods.

This description agrees rather closely with that of the structures observed in typhus blood by Ricketts and myself and with the observations of several of the more recent investigators. It would seem that many of us have been interested in the same organism. If later work bears out these earlier studies, typhus fever must be included in the group of insect-borne bacterial diseases and grouped together with plague and Rocky Mountain spotted fever. It is worthy of note that both of these diseases are caused by bipolar bacilli that resemble the organism probably responsible for typhus. This close relationship of typhus with plague and Rocky Mountain spotted fever was suspected by Ricketts some time before our investigations of typhus were undertaken.

STUDIES CONCERNING DIABETES *

FREDERICK M. ALLEN, M.D.

NEW YORK

The work, of which this paper will give a synopsis, is the continuation of an experimental study of diabetes described in detail elsewhere.¹ Certain of the results of the previous investigation, bearing on the present topic, may be summarized under the following four headings:

1. Production of Diabetes: Removal of portions of the dog's pancreas produces a lowering of the sugar tolerance. Removal of nine-tenths of the gland results in severe diabetes. When the remnant is larger (for instance, one-eighth), milder types of diabetes result. The course is chronic, extending over months, and the end fatal. Such animals furnish a closer imitation of human diabetes than is produced by total pancreatectomy.

2. Pathologic Anatomy of Diabetes: In the foregoing procedure, duct communication between the pancreatic remnant and the duodenum is preserved. Therefore the acinar tissue does not atrophy, and in some cases it may hypertrophy. The islands of Langerhans show typical progressive alterations, which may be summarized as vacuolation of cytoplasm and loss of granulation, pyknosis of nuclei, loss of cells, and

finally disappearance of islands. By suitable controls the changes were shown to be specific to diabetes. Homans² has made a careful histologic study of such changes in the islands of diabetic cats by the aid of the admirable methods of Bensley.

3. Pathologic Physiology of Diabetes: An idea has long existed that the disturbance of carbohydrate metabolism in diabetes might perhaps be explained by the assumption that sugar exists in a combined form in the normal body, but that this combination is lacking in diabetes. In the diuretic behavior of dextrose in diabetic and non-diabetic animals, I found contrasts which were interpreted as evidence in favor of this conception, which was therefore put forward as a hypothesis to explain the various phenomena of diabetes. The combining substance was designated by the figurative title of "amboceptor," to indicate its function as a bond between tissue and sugar. The substance which thus combines with dextrose, or some link in the combination, is supposed to be furnished by the islands of Langerhans. For details concerning the hypothesis and the evidence, reference must be made to the original publication.

4. Prevention or Checking of Diabetes: Under certain conditions the presence or absence of experimental diabetes may be determined by the patency of the pancreatic duct. When the pancreatic remnant is sufficiently small, diabetes results, even if this remnant is cut off from duct communication. But, with a slightly greater size of pancreas-remnant, it is possible under favorable conditions in certain cases to show that diabetes occurs if the duct is patent, but remains absent if the duct is ligated. Particularly in one instance it was shown that a diabetes already begun stopped when the duct was ligated. The period during which diabetes can thus be prevented is necessarily limited, since ligation of the duct produces in the dog gradual atrophy and degeneration of all the elements of the pancreas, and this gives rise after weeks or months to the Sandmeyer type of diabetes.

PRESENT INVESTIGATION

The present research has advanced along the same lines as the preceding one, and has kept in view the same clinical purpose.

I. PRODUCTION OF EXPERIMENTAL DIABETES

A. By Operation

Of several species of animals tried, the dog and cat are the most convenient and useful. Rapid death from cachexia, which I previously described as an occasional occurrence in dogs, is more frequent in cats. In them diabetes is intense and life short after removal of nine-tenths of the pancreas; but by removal of fractions such as three-fourths, four-fifths and five-sixths of the pancreas, one obtains mild or severe forms of diabetes as desired, and such cats live for weeks or months. In cats, more readily than in dogs, can thus be produced mild, transitory, intermittent forms of glycosuria, doing the animal little or no harm, and determined largely by diet (as milk, or sometimes even the feeding of liver instead of ordinary meat). There is a decided tendency toward recovery, though aggravation can often be produced by continuance of improper diet. This form of diabetes may be compared to those mild, intermittent, relatively benign

human cases which some persons have supposed to be not of pancreatic origin.

With respect to dogs, the figures given above concerning size of pancreas-remnants hold good for medium-sized animals, such as were convenient for the purposes of the previous research. Present findings indicate that the size of the pancreas in proportion to body-weight in large and small dogs may vary considerably, and that the size of the pancreas-remnant which permits diabetes may vary correspondingly, though a longer series of observations must be completed before making more precise statements. In cats variations of this character are absent or less marked.

B. By Diet

The papers of Thiroloix and Jacob, previously reviewed, report success in a line of experiment in which earlier workers failed. They state that some dogs after partial pancreatectomy are free from glycosuria on meat diet, but show glycosuria when carbohydrate is fed; and that continuance of carbohydrate diet finally brings the animals into a state of severe diabetes in which they excrete sugar even on meat diet. The reports of the French authors are brief, and contain no mention of controls or proof that such dogs might not ultimately develop severe diabetes, even without carbohydrate feeding. These may perhaps be the reasons why this discovery has received practically no notice in the literature. Independently of these writers I had made similar observations, and believing them to be of importance, I have repeated and extended the work. Based on the experiments so far conducted, it is possible to make the following statements:

1. After removal of sufficiently large fractions of the pancreas, as above described, dogs develop a severe diabetes, in which they show heavy glycosuria on meat diet and also during considerable periods of fasting. The condition progresses steadily downward to a fatal end.

2. When the remnant of pancreas left *in situ* is slightly larger, a condition may be produced in which the fate depends on the diet. On meat feeding such a dog is free from glycosuria and remains so for months, eating his fill every day and maintaining full health and nutrition, with no sign of downward progress; but subcutaneous tests show that the dextrose tolerance is very low, and bread feeding readily produces glycosuria. A return to meat diet stops the glycosuria; but if the bread diet and accompanying glycosuria are maintained for too long a time, the glycosuria then continues, even on meat feeding. The diabetes thus produced is not inferior in severity to that resulting from simple removal of larger fractions of pancreatic tissue, and the downward course and fatal termination are similar.

3. When the pancreas-remnant is still larger, glycosuria is absent on meat diet, and on bread diet may be absent or transitory. Such animals may remain in excellent condition indefinitely on bread diet, free from glycosuria or any downward tendency; but if sufficient sugar is added to the diet, glycosuria can be produced and maintained. After a period of such glycosuria, the animal reaches a condition in which it is glycosuric on bread diet. By prolonging the glycosuria on bread diet, the dog finally reaches the condition of severe diabetes, with glycosuria on meat diet, and continuous downward progress. For such sugar feeding I have ordinarily used commercial glucose. The

2. Homans, John: Jour. Med. Research, 1914, xxx, 49.

experiments succeed best in greedy dogs and those naturally fond of sugar. A decided aversion to sugar on the part of the dog may spoil such an attempt through failure of appetite.

4. When the pancreas-remnant is still larger, sugar feeding may produce transitory glycosuria, but it cannot be made to continue. The sugar tolerance is lower than in normal dogs, but nevertheless the doses of sugar necessary to produce glycosuria are higher than can be tolerated as a daily routine by the gastrointestinal canal. Persistence in the attempt to maintain glycosuria causes diarrhea and illness. The dog refuses to eat, sugar given by stomach-tube is vomited, and true diabetes remains absent. Similar results can be obtained with cats by feeding carbohydrate in the form of milk.

The changes previously described as occurring in the islands of Langerhans occur whether the diabetes follows directly on the operation alone, or has been induced in the prepared animal by means of modification of diet. The best of the control animals are still alive; but the control tissues thus far examined indicate that in animals predisposed by operation, when diabetes is prevented by carbohydrate-free diet, the signs of exhaustion and degeneration in the islands of Langerhans are absent. If further study shows that this is the case, it will afford additional evidence that these changes have a direct relation to the diabetes and that they are a result of functional overstrain.

While various factors are undoubtedly concerned in the production of human diabetes, clinical observations indicate that diet is an important one. It is generally recognized that there is a higher incidence of diabetes among those races or classes of people who use an excess of carbohydrate. Luxurious living and sedentary life are thought to predispose to this disorder. The experimental observations on animals suggest an explanation of this relationship between diet and diabetes in the human subject. If individuals differ in the strength of the pancreatic function as in other functions, in some this may be so weak that diabetes comes on in early life irrespective of the diet. In others this function may be only a little stronger, so that diabetes may be delayed until later in life or even to the period of senility, when there occurs an impairment of various functions. Others may be more or less below the average in pancreatic functional power, but under ordinary circumstances this is sufficient to prevent the occurrence of diabetes. In these persons, however, who might otherwise go through life with no sign of diabetes, an excess of starch in the diet may serve as an exciting cause of diabetes, and the degree of such excess may help to determine the earlier or later onset and the milder or severer type of the disorder. In other persons of this sort, as in the corresponding type of dogs, the pancreatic function is able to deal safely with as much starch as can be digested, but a sufficient excess of sugar is an effectual cause of diabetes.

It is impossible to produce diabetes in the normal dog by an excess of carbohydrate feeding, since if too much sweet or starchy food is taken, indigestion results and automatically stops the ingestion. But in dogs after operation and in predisposed human patients, pancreatic weakness may reverse the normal relation, so that the organism can digest and absorb more carbohydrate than it can combine and assimilate; and in this condition the production of diabetes by improper diet is possible. The question of diabetes may then be regarded as a balance between the digestive and assim-

ilative functions. Moreover, the body is equipped with no natural safeguards against this unnatural condition. There is no reflex or other mechanism which points plainly to the cause of the trouble and compels its cessation. On the contrary, the impaired nutrition due to failure of assimilation affects the organism as if it were due to deprivation of food. The response commonly shows itself in the harmful form of increased appetite. The taking of excessive food injures the assimilation still further, and thus a vicious circle results.

II. PREVENTION OR CHECKING OF EXPERIMENTAL DIABETES

The therapeutic experiments in animals pertain to two groups of cases, those in which diabetes is produced by simple operation, and those in which diabetes is produced by diet in predisposed animals.

1. Animals made diabetic by operation. In animals from which an excessive amount of pancreatic tissue is removed, a diabetes may be obtained which is so severe that fasting will not produce sugar-freedom. But when the pancreas remnant is of suitable size, for example, one-tenth, though the resulting diabetes is permanent on meat diet and will end fatally if allowed to persist, nevertheless a few days of fasting at the outset will produce sugar-freedom. If the diabetes is allowed to continue longer, a much longer period of fasting may be necessary for sugar-freedom, or it may be impossible to obtain. If, after obtaining sugar-freedom, feeding of protein and fat (with occasional bones) is begun very cautiously, in quantity only enough to maintain the animal in its thin condition, such dogs remain free from diabetes. The longest experiment to date is that of a dog which, possessing less than one-tenth of the pancreas, has been kept free from diabetes for six months, and there is at present no indication that the condition cannot be continued indefinitely. If an attempt is made to increase the weight of such an animal, glycosuria soon appears and must be checked by renewed fasting. Such dogs, though very thin, are vigorous and lively. They contrast sharply with dogs which, after similar operations, are allowed to remain diabetic on full meat diet. Though the latter animals at first appear much better nourished, they finally emaciate in spite of the most enormous eating; and when they have become as thin as the dogs above described, weakness and cachexia are very evident, and the progress continues downward to death.

2. Animals made diabetic by diet. When the animal possesses perhaps an eighth or a sixth of the pancreas, and is not diabetic after operation but is then made diabetic by excess of carbohydrate, this diabetes at first can be stopped by a simple change to meat diet. After a longer duration, the diabetes no longer stops on carbohydrate-free diet; but after a period of fasting, the time depending on the severity of the diabetes, the urine becomes sugar-free. With still greater duration or severity of the diabetes, sugar-freedom is no longer obtainable by fasting. When such animals are made sugar-free, they may be kept so by the same procedure as described for those of the former group. When the diabetes is thus checked fairly early, it is evident that the prognosis is much more favorable than in animals of the previous group, for in the present animals the removal of pancreatic tissue was considerably less, and the cause of the diabetes is partly a functional change. Accordingly, it is found that the

diet can be gradually increased, and in favorable cases the animals be brought to a higher level of weight and nutrition than is ever possible with dogs of the preceding type. Up to the present, however, the experience has been that these dogs are never able to return quite to the condition which they enjoyed before the diabetes, and which is permanently maintained by similar dogs in which diabetes is prevented by suitably chosen diet from the outset. As above mentioned, dogs so treated can be kept indefinitely at full weight and well-being when placed after operation on a diet which keeps them free from glycosuria. But when diabetes gravis has been produced and allowed to continue long enough to demonstrate its reality, while it has been possible by the foregoing method to stop the diabetes and bring a dog back to within a kilogram of its normal weight, every attempt to produce a further gain in weight has brought a return of glycosuria, which must be checked by fasting. Such dogs, however, are so near to normal that, if they are mixed up in a yard with ordinary dogs, a stranger might be unable to tell one from the other.

The microscopic examinations of the pancreas remnants of such animals as have yet come to necropsy from both of these groups show that in both alike the island cells are well endowed with cytoplasm and granules, and degenerative processes are not seen; but there is a decided impression that the islands are inferior in both size and number to those of normal animals. If this impression proves valid in further experiments, a correlation readily suggests itself between the observed anatomic change and the diminished pancreatic function described in the preceding paragraph.

In my previous report I have shown that by removal of suitable fractions of the pancreas, animals may be brought so close to the verge of diabetes that the removal of less than a gram of additional pancreatic tissue suffices to bring on diabetes. According to the "amboceptor" hypothesis, the pancreas furnishes some definite substance or substances used by the cells of the body for the metabolism of carbohydrates and perhaps also of other foods, the "amboceptor" being used up in metabolism and bearing some quantitative relationship to the metabolism. Extending this theory to the foregoing experiment, one may say that the fragment of pancreas which barely prevents diabetes is the smallest fragment which can supply the minimum quantity of "amboceptor" necessary for the animal's metabolism. When such a pancreatic fragment is even slightly reduced, the supply becomes slightly deficient in quantity, and diabetes accordingly begins and runs the usual downward course.

Present observations prove that the reverse of this experiment is likewise possible, that is, when an animal and its food consumption are suitably reduced, a pancreatic remnant otherwise inadequate becomes adequate; diabetes under these conditions may be prevented or be checked after it has appeared. Prevention or cessation of diabetes previously observed in consequence of ligation of the pancreatic duct may be explained by the impaired food absorption and chronic malnutrition of the animal. Similarly in dogs which develop distemper after the pancreatic operation, and which therefore refuse food and emaciate rapidly, diabetes may fail to appear or may stop after it has appeared. Interpreting these experiments on the basis of the "amboceptor" hypothesis, one may say that an otherwise insufficient amount of "ambo-

ceptor" may become sufficient when the metabolism of the body is artificially diminished.

III. CLINICAL TREATMENT OF DIABETES

In the clinical literature of diabetes there are authentic reports of certain cases in which even severe diabetes has cleared up spontaneously and completely on the onset of cirrhosis of the liver, cancer, tuberculosis or some other wasting condition. Other cases have notably improved. Probably the most severe and certainly the best studied of such examples was presented by one of Joslin's patients,³ in whom a long-standing and dangerous acidosis disappeared entirely, and a negative carbohydrate balance became positive, following the onset of tuberculosis. When these cases are considered in the light of the experimental study of animals, the possibility is suggested that we have an indication for a rational method of dealing with diabetes, or impaired pancreatic function associated with overstrain.

Notice should be taken of the advantage possessed by most diabetic human patients over diabetic dogs. Even the most hopeful of the above-described dogs has only a small fraction of the pancreas. Most of the organ is hopelessly gone, and the presence or absence of diabetes is determined by functional influences acting on the little remnant. Furthermore, even when the diabetes is inaugurated by functional means, the organic degenerative changes quickly ensue in the islands of Langerhans. Under these conditions it is surprising that results are obtainable by treatment at all. On the contrary, in typical human diabetes the entire pancreas is present, and there are indications that functional disturbance is an important factor.

It has been thought justifiable, therefore, to undertake the treatment of a limited number of patients by a method based on the principles derived from the experimental work as indicated in this communication. The number of patients so far treated is limited, but the results obtained indicate that the same method employed in rendering the diabetic dog free of glycosuria and prolonging its life is efficacious in eliminating glycosuria and acidosis in the human patient. To what extent life may be prolonged by this method only a large statistical study will show. The observations so far indicate that the method is not harmful, and when carried out carefully seems definitely beneficial.

The method of treatment is in brief as follows: If the patient is moderately emaciated, with a negative carbohydrate balance and acidosis, he is put to bed and receives no food whatever. If coma seems imminent the usual emergency treatment with purging, stimulants, alkalies and large amounts of water should, of course, be carried out. In addition to fasting, alcohol is important in the treatment at this stage. From 50 to 250 c.c. of whisky or brandy may be given in each twenty-four hours in small doses, from 10 to 20 c.c. every one to three hours during the twenty-four. As soon as the glycosuria stops and the acidosis diminishes, which even in severe cases may be within forty-eight to ninety-six hours, the amount of alcohol and alkali may be reduced. Fasting and moderate dosage of alcohol are continued for from twenty-four to forty-eight hours longer, however, depending on the patient's strength. The alkali is now stopped, and feeding with starch is commenced in order to clear

3. Benedict, Francis G. and Joslin, Elliott P.: A Study of Metabolism in Severe Diabetes, Carnegie Institution of Washington, 1912, Case R, p. 55.

up the last traces of ketonuria. The kind of starch is of minor importance. Green vegetables are useful because their carbohydrate and food value is so low that they can be given in considerable bulk, and this bulk is agreeable to the patient for relieving his feeling of emptiness. Neither fat nor protein is added. For the first day, the food is chosen to represent a carbohydrate content of from 10 to 40 gm. This is divided into four to ten equal portions and fed at equal intervals during the day. If glycosuria remains absent, the ration for the next day is doubled, to represent 20 to 80 gm. of carbohydrate, similarly divided into numerous small portions. On the next day it is sometimes possible to increase the ration to 100 gm. of carbohydrate, without glycosuria. About this time, especially if glycosuria has appeared, another fast-day is interposed, from 50 to 200 c.c. of whisky being given. Present experience indicates that even in severe cases ketonuria may by this method be made to disappear entirely. Several repetitions of the foregoing routine may be necessary for this purpose. All food contains danger, tending toward either glycosuria or ketonuria. The carbohydrate of the diet is seldom reduced below 50 gm., and is preferably kept higher. If carbohydrate must be kept low, the total diet is kept low. The diet is so chosen that glycosuria, not ketonuria, is the signal of overstrain. Fasting-alcohol days are given not merely whenever this signal appears, but also at close enough intervals to prevent it from appearing, even every two or three days if necessary. If there has been no glycosuria, a slight addition to the diet is made after each fast-day. Each day's diet is calculated exactly, and the nitrogen-balance is watched. It is thought that no matter how low the assimilative power, the attempt to feed in excess of this power is harmful, and it is possible that by rest the assimilative function may gradually become stronger. With improvement in the patient's condition, the carbohydrate in the diet is further increased. Increase in weight, however, is not attempted at this time. From our present point of view, contrary to the generally held opinions, the attempt to increase weight should be the last rather than the first step in treatment. It is attempted to keep the metabolism at the lowest safe level until the patient is taking from 100 to 150 gm. of carbohydrate (mostly as green vegetables) daily, with fast-days interposed often enough to prevent any trace of glycosuria from appearing. Then protein is cautiously added, always being kept rather low; and in favorable cases the weight and well-being may finally improve under gradual additions of fat.

The radical procedure here described is that used for the most severe cases. In milder cases the treatment may be correspondingly milder. Primary loss of weight is intentional. The purpose of the treatment is not to confer temporary comfort or appearance of well-being, though various symptoms, including polyphagia and asthenia, may actually be relieved. When there is extreme cachexia and emaciation, the difficulty is greatest. It may then be necessary to juggle very carefully the three factors of glycosuria, acidosis and nutrition.

A report giving the results of this form of treatment in a series of cases will be published later. It is felt that the conception underlying this method of treatment, based on experimental observations, is new, though certain details have long been recognized as of importance. According to this method, alkali treat-

ment is not employed, unless for a brief period at the outset, while severe acidosis is being combated. The alkali treatment has been called the most brilliant discovery in the modern study of diabetic therapy. It is indeed a valuable means for facilitating the excretion of acetone bodies. But under an efficient treatment of diabetes, acetone bodies should not be excreted. They should be burned.

Though it seems possible thus to check all active symptoms, with apparent benefit, even in very severe cases, yet it is felt that the ultimate outlook for these patients is far less favorable than it would be if they could be treated earlier. The best therapeutic hope is believed to lie in the application of this principle of treatment at the earliest possible stage in diabetes.

ABSTRACT OF DISCUSSION

PROF. A. J. CARLSON, Chicago: Does Dr. Allen consider the evidence conclusive that mere obstruction of the pancreatic duct in dogs leads to the atrophy of all the elements in the pancreas? In the rabbit this is not the case. I have seen in dogs, in connection with other work, the islands persist for six or nine months, that is, enough of the island tissue to prevent diabetes.

DR. ALLAN C. EUSTIS, New Orleans: Has Dr. Allen noticed the appearance of the acetone bodies in the urine of these dogs; whether they were present during the fasting stages and how soon they would appear; and also whether the amount of the pancreas left in had anything to do with the rapidity with which the acetone bodies appeared?

DR. F. M. ALLEN, New York: Answering the latter question first, I have never seen a satisfactory reproduction of human acidosis in dogs. A few authors have reported considerable acidosis in totally depancreatized dogs, and even death in coma, but these cases are the exception rather than the rule. The difference between carnivorous animals and man as respects acidosis is one reason for attempting to reproduce diabetes in other species which are more like the human in this respect. With regard to Dr. Carlson's question, two factors must be considered; one is species, and the other is time. In rabbits and guinea-pigs, following ligation of the pancreatic duct, authors have proved that numerous normal-appearing islands of Langerhans are present long after the disappearance of all acinus tissue. The pancreas is described as being replaced by fibrofatty tissue and though the islands pass through phases of degeneration and regeneration, the island tissue is not permanently destroyed but apparently persists indefinitely. Such animals are free from diabetes, but it has never been proved that true diabetes can be produced in these species by any means. In dogs, on the other hand, ligation of the pancreatic duct is followed by scar-tissue formation, and islands as well as acini are destroyed. Such degeneration of a ligated pancreas-remnant gives rise to the Sandmeyer type of diabetes. In the dense fibrous tissue at the site of the pancreas in dogs dead from prolonged Sandmeyer diabetes, it is said that neither acini nor islands have been found. The time-element is involved in experiments such as Macalлум's, which undertake to show that islands persist at a time when all acini have disappeared, and that the dog at this time is not diabetic. Positive results in such experiments may furnish evidence in favor of the insular hypothesis; nevertheless after a longer time-interval the islands may be expected to degenerate and disappear. Indefinite persistence of islands in the ligated pancreas, as proved for the rabbit, has never been shown in the dog.

THE INFLUENCE OF SWEAT BATHS ON THE NON-PROTEIN NITROGEN CONTENT OF THE BLOOD IN NEPHRITICS*

J. HAROLD AUSTIN, M.D.

Associate in Medicine and Research Medicine, University of
Pennsylvania

AND

T. GRIER MILLER, M.D.

Assistant Instructor in Medicine and Henrietta Hecksher Fellow in
Clinical Medicine, University of Pennsylvania

PHILADELPHIA

The present study is based on the supposition that by the use of the recently acquired accurate methods for estimating the non-protein nitrogen of the blood, it might be possible to determine with greater precision than formerly the effects of sweat baths on the blood in nephritis. The sweat bath, advocated first for the removal of fluid from individuals with diseased kidneys, has more recently been extensively employed for the purpose of increasing the elimination of such solids as are normally excreted by the kidneys. Certain early observations seemed to afford a basis for such a procedure. It was found that in some nephritics, after sweating, a deposit was present on the skin which on analysis proved to be rich in urea. It was soon shown, however, that this phenomenon occurs only in agonal states or in conditions of extreme collapse when the permeability of the capillaries is quite abnormal and is in no sense comparable to that obtained under the conditions of the ordinary therapeutic sweat bath.

The chief method of approaching this problem experimentally has been by a study of the amount and composition of the sweat obtained. Both Strauss¹ and Bendix,² by freezing-point determination, found sweat to be of a lower concentration than the blood, from which it might be expected that sweating would lead to a greater concentration of the blood. Bendix failed, however, to demonstrate any lowering of the freezing-point of the blood after a sweat, and in one nephritic found an elevation. On the other hand, Georgopoulos³ noted in two nephritics a trifling, probably negligible, depression of the freezing-point of the blood after sweat baths. Von Noorden⁴ collected the sweat during sweat baths and estimated the quantities of nitrogen and of sodium chlorid recovered, and as a result found great variations in the output by different individuals, by the same individual at different times, and from different skin areas of the same individual. From his observations he concluded, however, that a nephritic, in the course of an hour's sweat, might excrete not more than 1 gm. nitrogen or 2 gm. sodium chlorid. In a very recent study Plaggemeyer and Marshall⁵ have estimated the nitrogen of the sweat obtained from fifteen normal indi-

viduals during a hot air bath lasting for twenty-five minutes after the onset of sweating. They found outputs of nitrogen ranging from 34 to 640 mg. The amount of nitrogen per hundred gm. of sweat ranged from 67 to 194 mg., a concentration much above the normal non-protein nitrogen concentration of the blood, and higher than that of most nephritics. Their study would apparently suggest the possibility of reducing the non-protein nitrogen concentration of the blood by such procedures.

Loofs,⁶ and later Tachau,⁷ studying the output of nitrogen and chlorids throughout the entire twenty-four hours in the sweat of non-nephritic as compared with nephritic individuals, reached different conclusions: the former finding a similar output in the two classes whereas the latter obtained, on the average, a slightly higher output in the nephritics, and a much higher output in one case of contracted kidney secondary to chronic lead poisoning.

Thus we see that hitherto the study of the value of sweating, in its influence on the nitrogen content of the blood, has been attacked chiefly by the estimation of the composition of the sweat itself. We feel, however, that, in the recently developed technic of Folin and Denis, we have at hand a means of attacking this problem more directly, in that it is possible to determine the composition of the blood itself, as regards its nitrogen content, before and after sweating. For this purpose we have made use of eleven patients of the type that customarily receives sweat baths for therapeutic purposes.

† Figures indicate milligrams of total uncoagulable nitrogen per hundred c.c. of blood.

TECHNIC

Each patient was given a sweat bath lasting from twenty to thirty minutes, during which he was made to sweat profusely, and was given at the same time all the water desired by mouth. When the patient was able to be up an electric cabinet bath was employed, but when confined to bed an ordinary vapor bath was used. The blood was taken from a vein at the elbow before and after the bath, 5 c.c. being used for each estimation.

The technic used for the determination of the total incoagulable nitrogen has been that of Folin and Denis, except that we have collected the ammonia in the final stage in fiftieth-normal hydrochloric acid and titrated with fiftieth-normal sodium hydroxid instead of nesslerizing. We have found titration to be as accurate and more simple and less time-consuming than nesslerization for the estimation of total nitrogen. Duplicate analyses were made, except in a few

instances; the greatest difference permitted being 0.1 c.c. of fiftieth-normal sodium hydroxid. Usually the titrations were identical or varied by only 1/20 c.c. fiftieth-normal sodium hydroxid.

With one exception our cases are all instances of chronic arterial hypertension; in some the phenolsulphonephthalein output was low and there was a moderate or marked increase of the incoagulable nitrogen of the blood; in the others, however, the phenolsulphonephthalein output was normal or nearly so and there was little if any nitrogen retention.

The last case is of especial interest, being an instance of acute mercuric chlorid poisoning with suicidal intent. The patient developed total anuria within twelve hours of the taking of the poison, and this had persisted until the time when our analyses were made, thirty-six hours later. In his vapor bath this patient sweated very freely.

The blood was in all cases taken immediately before the bath, and the second sample in some cases immediately after the bath, in other cases from one to four hours after the bath. Our results are shown in the table and may be summed up in the statement that no change of significance was observed in the concentration of the non-protein nitrogen of the blood as the result of the sweat bath.

In conclusion therefore, without any intention of denying a possible therapeutic value from sweat baths, we find no evidence that they lead to any significant change in the concentration of the non-protein nitrogen of the blood.

THE USE OF ATOPHAN AND RADIUM EMANATION IN THE TREATMENT OF GOUT AND THE ARTHRITIDES*

ARTHUR F. CHACE, M.D.

AND

MORRIS S. FINE, Ph.D.

Professor of Medicine and Lecturer in Pathological Chemistry, respectively, in the New York Post-Graduate Medical School and Hospital

NEW YORK

Medicine has long awaited a therapeutic agent which would induce a significant increase in the output of uric acid. Before the introduction of atophan, aside from the salicylates, there was no drug which could be relied on to bring about this condition. During the six years of its history, abundant data have accumulated demonstrating that atophan may increase the elimination of endogenous uric acid from 50 to 200 per cent., and the mechanism by which atophan acts has been the object of much investigation. Disregarding the several views held concerning this point, we may say that at present the simplest and most satisfactory explanation is to be sought in an increased permeability of the kidneys, by which the level of uric acid retention is lowered, thus permitting a draining of this substance from the blood and tissues. While there are occasional scattered data in the earlier literature on atophan which appear to favor this view, nevertheless the idea may be said to have received its first experimental support when Folin and Lyman,¹ by

means of the Folin-Macallum colorimetric method, demonstrated an unquestionable decrease in the uric acid concentration of the blood associated with the augmented output in the urine. These observations have since been confirmed by McLester,² Steinitz³ and ourselves.⁴

Whatever may be its cause, gout is undeniably characterized by a concentration of blood uric acid which is from two to five times as great as that observed in normal individuals. Whereas, in the majority of normal individuals one finds 1 to 2.5 mg. uric acid per hundred grams of blood, in gout it is in general as high as 4 to 6 mg. Since the principle of treatment in gout is to avoid purin foods and to maintain the uric acid of the body tissues as low as possible, it would seem that an agent which is essentially a specific eliminant for uric acid, as atophan appears to be, would form a rational therapy in this condition. It then becomes desirable, to learn the details attending the action of this drug.⁵ We have found that the action of atophan on the blood uric acid begins to make itself felt within two or three hours after its administration, that is, as soon as absorption has taken place, and reduces the blood uric acid to a minimum concentration within about two days. This minimum concentration appears to vary for different individuals from 0.7 to 2.5 mg. per hundred grams of blood and cannot be further lowered even when the drug is administered continuously for a month and a half. The original level of uric acid concentration is nearly reattained after the use of the drug has ceased for two days.

Under treatment with atophan, all of the five cases of gout showed improvement of more or less permanence, as did also four cases of possibly gouty nature. Of the eleven cases of arthritis of various types, two showed some improvement. A superficial summary of clinical results of this character cannot, however, convey an adequate view concerning the value of the treatment. Thus, in one case of gout, there was almost immediate improvement after taking atophan, which persisted even after the cessation of the use of the drug, and in spite of the return of the uric acid concentration of the blood to the original level; while in another case of gout, the initial improvement became less pronounced in spite of the continued use of atophan and the maintaining of the blood uric acid at less than half its original level. We shall reserve a more careful analysis of the clinical results until we have had an opportunity to extend our observations over a longer period of time.

In contradistinction to gout, arthritis is not characterized by an excessive concentration of uric acid in the blood; and this difference, in our experience, has been of aid in distinguishing between these conditions. Thus in one case, which by several clinicians was regarded as typical gout, there was a constant uric acid concentration of but 2 mg. per hundred grams of blood. A careful investigation disclosed a colon bacillus infection in the pelvis of the kidney, which was cleared up under the administration of the appropriate vaccine, whereupon all "gouty" symptoms disappeared. We are not yet prepared to assert that a high concentration of uric acid is essential for a

diagnosis of gout, but our experience with those cases of joint and muscle involvement associated with a uric acid concentration of less than 2.5 mg. has indicated the desirability of a diligent search for foci of infection in various parts of the body, which may be the primary cause of the joint affections.

The improvement noted in certain cases of arthritis can hardly be explained by an influence on the elimination of uric acid. The usual lowering of the uric acid concentration of the blood is indeed noted, but there is no reason to regard uric acid as a factor in the etiology or progress of arthritis. In such cases there appears to be an analgesic action, which may likewise to some extent account for the relief felt by gouty individuals.

With regard to the influence of radium emanation on uric acid metabolism, various European workers have emphasized essentially two points: the increased elimination in the urine and the reduction or disappearance of uric acid of the blood. The increased elimination of uric acid in the urine under the influence of radium emanation is perhaps due to the induced leukocytosis with subsequent leukolysis. In the light of recent developments in purin metabolism, the disappearance of uric acid from the blood as noted by Gudzent⁶ is a most unusual observation. It has not been supported by beaker experiments or by our own studies.

We have thus far treated thirteen cases of gout and arthritis in an emanatorium with radium emanation of 0.5 to 150 Mache units per liter of air in one- to two-hour sittings for one to two months; two cases of arthritis with radium drinking-water; and five cases of arthritis with injections of radium bromid equivalent to 50 to 100 micrograms of the element. In no instance was there any change whatever in the uric acid concentration of the blood. In view of these findings we can hardly subscribe to Gudzent's claim that with concentrations of radium emanation of as little as 2 to 4 Mache units per liter, uric acid disappeared from the blood and remained absent as long as one year.

With regard to clinical effects, we may say that in only two instances—those in which radium solutions were injected—did there appear to be any improvement. Here again, however, we feel that the treatment should be extended over a greater interval, before conclusions can be properly drawn with regard to clinical results.

ABSTRACT OF DISCUSSION

DR. CHARLES G. STOCKTON, Buffalo, N. Y.: With reference to the effect of atophan in relieving the uric acid burden of the blood we have given the drug in studies of the blood, including the method of Folin. The drug has acted unpleasantly in some instances, although usually it occasioned no trouble. One other question is what is commonly meant by the term gout. Dr. Chace spoke as though gout was a condition parallel to excess of uric acid in the blood, or uricacidemia. Gout is something in addition to an excess of uric acid in the blood. Just what that something is remains to be seen. In one case coming to my attention the patient had 25 mm. of uric acid in 100 c.c. of blood when not treated, but after long-continued dietetic treatment and the use of atophan he was discharged with 8 mm. of uric acid to 100 c.c. of blood, and yet he had no gout. He had had an attack of gout ten years before. At the same time I had two cases of gout under treatment, one patient having 5 and the other 7 mm.

of uric acid to 100 c.c. of blood; one was treated by atophan and the other by colchicum and both by alkalies; the results were compared. I saw but little difference, save that the atophan seemed to have rather the better effect in reducing the uric acid. The clinical course of the two cases was much alike, both having been severe and typical gout.

DR. S. SOLIS COHEN, Philadelphia: For a number of years I have been making use of atophan and novatophan in the treatment of chronic gout. I agree with Dr. Stockton that uric acid is not by any means the whole story in gout, nor do clinical results always run parallel with the reduction of the uric acid content of the blood whether under the administration of atophan or the use of radium emanations. The most striking effect, clinically, of atophan in gout, rheumatoid arthritis and acute articular rheumatism is the relief of pain. In rheumatic fever the administration of atophan was always accompanied by relief of pain and fall in the temperature, but its withdrawal was followed by a recrudescence of pain and fever. It did not bring about recovery. For this, resort to salicylates was necessary. In cases of chronic gout, or in patients having a distinct gouty tendency, atophan given for one week in the month over a period of several months is helpful. Large doses are not needed, 1 gm. a day (divided into three 5-grain doses) is sufficient. It is not necessary to reduce the uric acid content of the blood to a theoretically normal standard. Gouty people have a higher normal uric acid index than others. It is only when this is exceeded that symptoms result. This is a natural consequence of evolutionary adaptation affecting every cell in the body. While 7 mg. or even 4 mg. per hundred cubic centimeters of blood is excessive for a normal man, it may not be equally excessive for one of gouty heredity. When the quantity of uric acid has been reduced to the equilibrium-point for the individual one should be satisfied; one does not hope to make the gouty cells of an entire body normal. With radium emanations I have had some experience and also with radium drinking-water but I have not sufficient data as yet for positive conclusions. In my dispensary service at Jefferson Hospital my assistants have made careful clinical observations which seem to show that better results can be obtained in the acute cases than in the chronic ones. It is possible that the remedy was not used long enough or strong enough. Our solution equals 50,000 Mache units per liter. The first effect of the radium treatment in cases of painful joints whether of gouty, rheumatic, or other origin, is to increase the pain, that is, providing one gets any effect at all. Unless one gets this exacerbation my observations have been that one cannot hope for a curative result. Apparently the agent acts on a sluggish local process, and reawakens the corrective reactions.

DR. ARTHUR F. CHACE, New York: In reply to Dr. Stockton, we have found that those patients having an intolerance for atophan can take it, well diluted with water, in small doses or in combination with soda. Novatophan has not proved as efficient as atophan. The determination of the uric acid content of the blood will aid in more accurately diagnosing cases of gout. We do not call a case gout unless there is a concentration of uric acid of 4 mg. per hundred cubic centimeters of blood. It is interesting to note in other conditions the high uric acid content of the blood; for example, in uremia we have found a concentration of 14 mg. uric acid to 100 c.c. of blood. The amount of the uric acid content of the blood is an index of the severity of the case. In all clinical cases of gout in which there is a low uric acid concentration it is well to look for a possible focus of infection. With regard to the method of administration, it is wise to do as Dr. Cohen suggested, give the drug for one week in one month, or else alternate giving atophan for four days and allowing an interval of four days. In all cases the patients are placed on a purin-free diet. With purin-free and alcohol-free diet and without the use of drugs we have seen the uric acid content reduced from 6 to 3 mg. per hundred cubic centimeters of blood. With regard to the clinical influence of radium, we prefer to reserve our judgment until we have had an opportunity to extend our observations.

New Instruments and Suggestions

THE SLOANE HOSPITAL INCUBATOR

EDWIN B. CRAGIN, M.D., NEW YORK.

Professor of Obstetrics and Gynecology, Columbia University, College of Physicians and Surgeons

To the different varieties of incubators which have been in use for many years there have been three common objections: insufficient air space; insufficient circulation of air, and difficulty in maintenance of a constant temperature.

Impressed with these objections I have sought to overcome them:

1. By having the incubator built several times larger than those in common use.

2. By maintaining a gentle current of filtered air passing through it. The air enters through a gauze screened opening below and is sucked out by a small electric fan above.

doors of beveled plate glass set in nickel-plated brass frames. At each end is a beveled plate-glass window $24\frac{1}{2}$ inches by $20\frac{1}{2}$ inches. In the interior directly behind each set of doors is a basket or cradle, built of nickel-plated brass wire and supported on hooks, in which the infant lies. Beneath each cradle is a tray which contains water for keeping the air moist. The condition of the air is indicated by a hygrometer and its temperature by a thermometer, both of which are visible through the glass doors. Beneath each tray is a series of violet-colored incandescent lamps which furnish the heat which is distributed by means of a heat disbursor. On the roof of the incubator a small motor with a fan and the necessary resistance is enclosed in a metal chimney leading from the interior. The motor is controlled by a rheostat situated outside of the incubator between the two front windows. The lamps are connected in series of two on each side controlled by snap switches (as shown in the illustration) which in turn are connected with the house current. Directly inside of each door is a small pilot lamp. When the incubator is in operation the air enters through the intakes,

Infant incubator; 1, resistance lamp; 2, heating lamps (violet); 3, motor for exhausting air; 4, thermometer; 5, hygrometer; 6, air intakes; 7, humidity tray; 8, cradle; 9, motor regulator; 10, heating lamp switches; 11, pilot light.

3. By maintaining a constant temperature by different series of electric lights which may be turned on or off in series.

This incubator, which was built for me by the Hospital Supply Company of New York, and of whose hearty cooperation I wish to express my appreciation, has now been in use with two of its fellows at the Sloane Hospital for Women for one year. It has met its requirements well; has demonstrated its superiority over the old types of incubators with small chambers heated by a water tank to which a gas burner was applied, and in the growth and development of the premature babies kept therein has proved a most valuable addition to the hospital.

The mechanical description of the incubator is as follows:

It is built entirely of steel finished on the outside in aluminum bronze and painted on the inside with gray enamel. It consists primarily of the incubator proper which is $84\frac{1}{2}$ inches in length, $46\frac{1}{2}$ inches in height, and $30\frac{1}{2}$ inches in depth. It is supported on legs 30 inches high, making the total height $76\frac{1}{2}$ inches. In front at each side are two double

comes in contact with the heat-disbursing plates and passes throughout the interior. By means of the motor fan a continual gentle current of fresh warm air is kept circulating through the incubator. The degree of heat is regulated by turning on more or less of the snap switches and by proper regulation of the motor.

Feeding Humans According to Formulae.—The study of human nutrition has not yet produced a simple formula for man's guidance in the selection of his food. Such formulae have been successfully used in the feeding of rats, and the skilful stockman in his feeding operations carefully follows charts and rules provided him by experts on animal nutrition. We may expect that similar rules will obtain more and more in human nutrition and there will be, some time in the future, such a thing as scientific feeding of men.—J. H. Lyman, *Popular Science Monthly*.

THE NATURAL YELLOW PIGMENTS OCCUR- RING IN THE BODY

"Luteins" or "lipochromes" are names that have long been current to designate the pigment or group of yellow pigments which may lend color to portions of the body rich in fats or to oily secretions derived from the organism. The identification of these yellow coloring-matters has usually depended on their spectroscopic properties. The lipochromes were associated with the fats and lipid substances, not only because of their solubility in these, but also because they showed similar behavior toward fat solvents like ether and insolubility in ordinary menstrua like water. The more or less apparent resemblance of the colors of egg-yolk, the corpus luteum, some blood-serums, sebum, milk-fat, etc., was indicated by the use of a common term, "lipochrome," to cover the pigments of all these animal products. The differences between the so-called lipochromes, represented by slight variations in the solubilities and other properties have become magnified by comparatively recent demonstrations. It has been shown that the pure "lutein" of egg-yolk is isomeric with the crystalline xanthophyll of green plants;¹ whereas the lipochrome of the corpus luteum has been identified as a true carotin.² The difficulties involved in this modern chemistry of the animal pigments will be appreciated from the statement that only 4 gm. of crude crystalline pigment were obtained from 6,000 hen eggs, and less than 0.5 gm. of crystalline carotin from 10,000 cow ovaries.

Following these demonstrations of the nature of some of the animal lipochromes, the origin and physiologic relationships of these natural yellow pigments have been cleared up at the dairy chemistry laboratory of the University of Missouri, in cooperation with the United States Department of Agriculture.³ The fat

of cow's milk owes its natural yellow color to the pigments carotin and xanthophylls — principally carotin, the well-known, wide-spread, yellow vegetable pigments found accompanying chlorophyll in all green plants. The carotin and xanthophylls of milk-fat are not synthesized in the cow's body, but are merely taken up from the food and subsequently secreted in the milk-fat. When a milk-giving cow is fed with food practically free from carotin and xanthophylls, such as the cow usually receives during the winter months, the immediate supply of these pigments in the organism is greatly depleted and may be entirely used up, on account of the constant drain on the supply by the milk glands. The butter-fat accordingly approaches a colorless condition in proportion to the supply of carotin and xanthophylls in the system, the length of time these pigments are kept out of the food, and also very probably in proportion to the amount of milk-fat being produced. If food rich in carotin and xanthophylls is fed to a milk-giving cow whose milk-fat has become practically colorless by reason of the conditions above described, the organism will at once recover its lost pigments and the milk-fat will increase in color in proportion to the amount of carotin and xanthophylls, especially carotin, in the food. Fresh green grass, being probably the richest in carotin of all natural dairy cattle feeds, accordingly produces the highest-colored butter. There is some difference among the different breeds of dairy cows with respect to the maximum color of the milk-fat under equally favorable conditions for the production of a high color. Each breed of cows, however, will undergo the same variation in color of the milk-fat which follows a withdrawal or addition of carotin and xanthophylls, especially carotin, to the food.

The yellow lipochrome of the body-fat, corpus luteum and skin secretions of the cow, like the lipochrome of butter-fat, is composed principally of carotin, which sometimes has associated with it one or more minor xanthophyll constituents. The carotin and xanthophyll pigments of the body-fat are derived from the food of the cow.

In the light of these interesting facts discovered by Palmer and Eckles with regard to the nature of the pigments of milk-fat and body-fat and their simple physiologic relation to the carotin and xanthophylls of the food, it is not surprising to find that the hitherto practically unknown lipochrome of the blood-serum of the cow is also chiefly carotin and bears the same relation to the food as the milk-fat carotin. We are thus able to establish the connecting link between the food carotin and the carotin of the milk-fat, body-fat, corpus luteum, etc., of the cow. Associated in small quantity with the carotin of the serum, probably dissolved in the fat of the blood, are one or more xanthophyll pigments which are always found in more or less variable quantity associated with the carotin of

plants. A variation in the quantity of these pigments in the food results in a corresponding variation in the amount found in the blood-serum and milk-fat. Body-fat formed during this time will also be affected. The government investigators believe that the carotin is carried by the blood-serum in a firm combination with a protein.

The demonstration of the interrelation of food pigments and body lipochromes in cattle applies equally well to man in so far as the available evidence indicates. The fat of human milk may be tinted with the same pigments found in the fat of cow's milk. The relative proportion of carotin and xanthophylls in human milk is much more nearly equal than in the fat of cows' milk. This is not surprising when it is considered that there is strong evidence that the xanthophylls are conveyed through the body dissolved in fat, and when it is also considered that fat plays a much greater part in human food than in the food of the cow. The fat of the human body is often characterized by a marked yellow color. In view of the fact that the pigments of the milk-fat and body-fat of the cow are identical it must therefore be concluded that the pigments of the milk-fat and body-fat of human beings are also identical.

SCHOOL HYGIENE

The study of conditions surrounding school life which may injuriously affect the growth and development of the child, and proper appreciation of the related subject, the hampering influence of physical defects on the intellectual capacity of the young, have until quite recently received little consideration in this country.

The first attempt, probably, to exercise medical supervision of schools in the United States was by the city of Boston, in 1894, for the purpose of controlling the so-called contagious diseases of childhood. From this beginning, the movement has developed until now most of our cities maintain a more or less comprehensive supervision over all matters pertaining to school hygiene and the medical inspection of school-children is mandatory in a number of states and elective in some others.

In this respect we are considerably behind European countries, notably Germany and England, where the system of medical school supervision is more extensively developed, has been longer in operation and is practically national in character. That this is so is largely due to the fact that consideration of the related triad, dirt, destitution and disease, has not been of such immediate importance with us, except in certain restricted areas.

School hygiene is a complex problem. It is generally conceded that our knowledge of its principles is greatly in excess of their practical application. The position of school medical officer presupposes, in addi-

tion to thorough training in physiology and psychology, a practical working knowledge of the physics of heat, light and ventilation, and an ability to recognize and coordinate the physical condition and educational needs of the developing child.

The need of skilled services and the expense incident thereto have been instrumental in restricting the practice of school hygiene largely to urban communities. This is unfortunate, because the great bulk of the school population of this country is as yet scattered over the rural districts.

The disproportionate prevalence of preventable diseases among urban and rural populations is not great; the necessity, therefore, of educating rural communities to the exercise of sanitary precautions necessary for the preservation of health is apparent. The importance of school hygiene in this respect is paramount, because the sanitary redemption of the majority of rural communities must largely be brought about through the practical education of the young in orderliness, cleanliness and the observance of sanitary precautions. Furthermore, the medical inspection of schoolchildren is in more or less intimate relation with the homes, which in turn are component parts of communities. The educational effect of school hygiene extends through these channels for the betterment of the community health.

The necessity for specialized medical services and the rather chaotic tabulation of the results of medical school inspections are largely responsible for deductions that do not bear analytic scrutiny. There is necessity for uniformity in methods of examination and of classifying the results for collective statistics to be of value. To state simply that a certain percentage of so many pupils have "defective teeth" may mean much or little. Certainly there is nothing in this classification to show whether the defect consists of one or more teeth needing attention or the presence of marked deformities. "Enlarged tonsils" do not always mean that the child should suffer the nervous shock attendant on a surgical operation; "diseased tonsils" are another proposition. Defects of vision and spinal curvature are frequently functional in character and due to "habits" of position acquired long before entrance to school, and have no connection with the equipment and arrangement of the classrooms. Much has been done along these lines, but there is need of uniform methods and systematic classification of results before these observations can be of value in studying mental and physical standards, and the effect of changing social conditions on development.

The object of school hygiene is primarily to place the impressionable child in the most favorable environment for physical and mental development and secondarily to detect and correct remediable defects which may impede intellectual training. The medical supervision of schools may, however, be further utilized by

the state in the determination of the prevalence of communicable diseases, especially in rural communities. The ultimate control of malaria, trachoma, tuberculosis and typhoid fever in these communities must be largely through educational methods. For these reasons the combination of the duties of the health officer with that of the medical supervision of schools appears eminently practicable. Furthermore, the health officer would have statutory authority to inspect premises, to abate nuisances and control foci of infection indicated by school medical inspections.

Intensive studies of the mental capacity of American schoolchildren, at varying ages, should be undertaken, in widely separated communities, with a view to the establishment of the normal mental standard, thereby rendering possible the study of the impress of immigration, and the effect of a changed social environment on the mental processes of the immigrant child, as revealed by similar examinations at the ports of entry.

THE VALUE OF HEALTH IN INDUSTRY AND WAR

There is food for reflection in the fact that the exigencies of commerce, the advantageous pursuit of industrial operations, and even the preparation for real or anticipated war may promptly bring about hygienic reforms which wide-spread preaching and earnest exhortation are at best slow in promoting. The "safety first" slogan which one hears in nearly every city of the United States at the present time is one aspect of a movement to increase the personal welfare of the individual by decreasing the liability to injury through the carelessness of a fellowman. The same spirit crops out in the "ten trade commandments" of the worker which are posted conspicuously here and there in factories where personal injuries and loss of life furnish unfortunate and—let it be frankly added—unprofitable incidents in the conduct of manufacturing operations. The reminder "thou shalt not" gains added force when its value is expressed in terms of practice and daily experience rather than in the more vague language of ethical considerations. And accordingly there is a telling force in such direct admonitions as the following, which we quote from a recent compilation for use in a factory:

"Thou shalt take no unnecessary risks, nor try to show off, nor play practical jokes, for by thy carelessness thou mayest do injury which will have effect unto the third and fourth generations to follow.

"Remember thou are not the only one on the job, and that other lives are just as important as thine own.

"Thou shalt not throw matches or greasy waste on the floor, as a dirty worker is a clumsy worker, and a clumsy worker is a menace to his fellow-workers."

These and similar timely suggestions, put in a form that is sure to attract notice, cannot fail to promote

the mutual and reciprocal interest of the employer and the employed. Modern hygiene and preventive medicine have recognized long ago that the individual can no longer claim a liberty in his actions, independent of his neighbor. Our provisions for quarantine, vaccination against small-pox, and diverse other regulations in the interest of the public health have, in the past, been enforced only with the annoyance that comes from lack of cooperation and from personal resentments together with the indifference for restrictive rules that is bred in a community of "free" people. Yet now we see, in the combined enterprise and altruism of modern employers, protective devices put in operation to secure, without friction or resentment, the same sort of welfare results that the federal government or state or municipality would find difficulty in getting under way.

That the unexpected situations created by war have, in the past, furnished the stimulus for new inventions and useful processes is too well known to require detailed comment. It would appear in the present situation that the war against universal peace may actually be a war against intemperance. The armies and navies of to-day represent the most efficient fighting forces that the nations can command. No device, no agency that will contribute to their power and preparedness, is willingly neglected. Health is a prime consideration in this respect. Field Marshal Earl Kitchener is reported to have counseled the English soldiers to abstain from drinking while abroad, reminding them that their duty cannot be done unless health is preserved. The men were cautioned to keep constantly on guard against excesses. The German Emperor is said to have forbidden the "treating" of the soldiers in his armies. The sale of absinthe, imported by French soldiers in an earlier war, when alcohol was used to fight fever, has been restricted in Paris.

It is of slight consequence whether or not these rumors are entirely correct. They represent the current tendencies, which are undeniable by anyone who has watched the recent decisions of American naval authorities in the face of not a little apparently adverse criticism couched in the usual phrases concerning personal liberty. The truth is, that "the relation of alcohol and fighting has been squarely met, and the fact admitted that they are not compatible." A recent editorial writer has expressed this by saying that a temperate army was something not conceived of in the old theories of war; but a drunkard is to-day as much out of place in an army as he would be on a battleship. As every great conflict, whether of church or state, of labor or commerce, has brought out some permanent good, however clouded it may temporarily have been by the major issues at stake, so the horrible strife which the world is now experiencing may actually be developing a war against intemperance—a permanent advantage of no mean proportions.

A NATIONAL STANDARD REQUIREMENT
FOR MEDICAL PRACTICE

The varying standards of medical practice in the several states have caused inconvenience and hardship from the time the states began to protect their citizens against incompetence and fraud. Complaint has frequently been made against the injustice inflicted on physicians who, after years of successful practice in one state, are obliged, before being permitted to practice in another, to submit to examinations on the same terms as if they were recent graduates. In one instance, at least, an eminent man with a national reputation was called on, when moving to another state, to undergo a written test of his ability and to remember text-book words, this test being administered, it was inferred, by one of his own former pupils.

Unlimited interstate reciprocity, on the other hand, is impracticable so long as the various states maintain differing standards for medical registration. A state which maintains a high standard obviously cannot be expected to reciprocate with a state which is satisfied with a low standard. Although the Constitution does not place the regulation of the practice of medicine among the functions of the federal government, nevertheless, it must be borne in mind that the Constitution does not prohibit the national government from assuming such a function should it be deemed desirable. The Constitution does not prohibit the establishing of a national standard or the making of such a standard obligatory. In practice, however, the national government has thus far left the control of these matters to the individual states. Not only is there no constitutional obstacle to the establishment by the general government of a standard for medical practice, and the provision of an examination, recognition of which shall at least be optional with the states, but, on the other hand, there are many strong reasons for such action.

Twelve years ago *THE JOURNAL* suggested¹ that all examinations for entrance into the various government medical services, instead of being given severally by the respective services, be given by one national board of examiners empowered to grant certificates or diplomas which should be a guarantee of a thorough and practical medical education and a prerequisite for candidacy for any medical position under the government. "The examinations should in part be conducted in hospitals and laboratories, so that practical and not theoretical knowledge would be demanded." The standard established should be such that, although its recognition as a credential for license by the state boards would be optional with the states, no state would have an excuse for refusing to recognize it. In fact, the practice acts of at least five states, Alabama, California, Colorado, Illinois and North Dakota,

provide that the licensing boards may license without examination physicians who have passed the examinations and served as officers of the United States Army, Navy or Public Health Service. The routine is practically the same in such cases as in carrying out the idea of reciprocity, so called. In either case there must be a voluntary relinquishment of rights on the part of the state, and the state can only give its examining or licensing boards the privilege of accepting the credentials of a corresponding board of another state.

The idea was taken up by Dr. W. L. Rodman² before the Committee on National Legislation of the American Medical Association later in 1902. He argued that the states would no doubt be glad to recognize diplomas or certificates issued, after a rigid, broad and practical examination by a board of unassailable standing. This would not interfere with the work of the state examining boards, for only the exceptionally able and ambitious graduate would care to try for the national diploma.

Lieut.-Col. J. R. Kean,³ in a recent address before the Federation of State Medical Boards, makes a practical suggestion toward the establishment of such a national examining board. The Secretary of War, he reminds us, is authorized to issue commissions as first lieutenants in the Medical Reserve Corps to graduates of reputable medical schools who pass an examination to be prescribed by the Secretary. No limit is placed on the number of reserve officers.

If, therefore, the President of the United States should appoint a board for the examination of officers for the Medical Reserve Corps, of a composition which would insure a high standard of requirement, and the state boards would agree to recognize without examination the holders of Reserve Corps commissions—as the states named above already recognize medical officers of the government services—the thing would be accomplished. If the laws of any state do not at present permit such recognition it would not be difficult to obtain the necessary legislation.

It would not be necessary to wait for favorable action by every state, for if the scheme were to be begun by even a few states, the rest could be expected to come into line as the desirability of the scheme became evident. It would obviously be desirable that the other medical services of the national government should join with the United States Army in a plan of such importance to the profession at large. The successful candidate would then have the qualification for a commission in the Medical Department of the Army, the Navy, or the Public Health Service, as well as a certificate of proficiency, "which would be the open sesame to the doors of state exclusiveness." As Kean

3. Kean, J. R.: The Use of the Government Medical Services in Raising the Standard of Medical Education, *Quart. Fed. State Med. Boards U. S.*, April, 1914.

1. National Board of Medical Examiners, editorial, *THE JOURNAL A. M. A.*, Jan. 11, 1902, p. 108.

says, "this board would not seek to examine a very large proportion of the recruits to the ranks of the profession or supersede, in any way, the state boards. . . . It is to do what a group of boards cannot do: to set a standard which all will accept; to be a mint which will stamp with its approval the good coin so that it will pass current in every part of the country, and not have to be weighed at every state line; to break down the barriers which, for acknowledged competence and ability, are unnecessary, vexatious and barbarous. It would be for the pace-makers and standard-makers of each year's crop of graduates; for the men who desire special honors or appointments; or for those who have migratory instincts and who may desire to enter some new field of work, and for whom the seal of approval of the general board would be valuable."

It may be of interest in this connection to note that Canada, which was confronted by a similar problem in the form of provincial rights that might not be gainsaid by the federal government, has surmounted the difficulty by the creation of a general medical council, whose registration the provinces had the privilege of accepting after the passage of permissive legislation. It is surely not to be imagined that so unfortunate an anomaly as our present chaotic system of registration is to remain an insoluble problem.

THE ALIMENTARY BACTERIA OF HEALTHY CHILDREN

The profound significance of the bacteria of the alimentary tract during the period of infancy is appreciated in a general way by every one who is concerned with the nutrition of children. It is nevertheless quite doubtful whether all of the manifold possible relations of the intestinal flora to the problems of health and disease are ordinarily comprehended by those who do not give considerable attention to the subject. Micro-organisms can, of course, injure the individual by becoming the agents of infection. Pathogenic bacteria find their way through the alimentary barrier and may bring about digestive or other nutritive disturbance as a secondary consequence of some systemic disease for which they are responsible. Far more commonly, however, the bacterial invaders initiate harm by their immediate, local action on the food materials which they meet in the gastro-intestinal canal. It is in this respect that our knowledge of the situation is still far from complete.

Broadly speaking, we realize that proteins, fats, and carbohydrates are altered in specific ways through the agency of bacteria. The limited character of this information is exemplified by the use of the indefinite expressions, such as the "putrefaction," "growing rancid," or "fermentation" respectively of the three great groups of nutrients. In a way, furthermore, it

is realized that the fermentative activities tend to preponderate over the putrefaction changes in infants when the diet is a natural one of milk. But there is nothing in such generalizations that is definite or specific enough to furnish very helpful guidance in times of alimentary trouble. The formation of abnormal products is never the result of the chemical processes of uncomplicated digestion. The harmful compounds arise only through the intervention of bacteria; the latter may belong to a specifically abnormal flora, or the normal alimentary flora may for some reason overstep the usual bounds of its activity and thus become abnormal in behavior rather than in its microbial character. Finally, ordinarily harmless organisms may completely change the nature of the products to which they usually give rise, if the character of the substratum that they subsist on is radically altered or other features of their environment become different. The intestinal flora of infants and young children therefore unquestionably deserves further study to determine more specifically than ever before the range of variety possible and the nature of the products which may be held responsible for physiologic effects of bacterial origin.

First of all and preliminary to a study of the morbid changes, it seems necessary to expand our knowledge of the conditions in health. A contribution has recently been furnished by Logan¹ from the research laboratory of the Royal College of Physicians at Edinburgh. His investigations agree in many respects with previous findings, notably the well-known experiments of Tissier.² In the intestinal flora of breast-fed infants—the ideal condition—the acid-tolerant group of organisms is immeasurably predominant, and is of the strictly anaerobic type called *Bacillus bifidus*. Coccal forms and lactose-fermenting bacilli are present, but scanty; spore-bearers are rare. In artificially fed infants the main difference is a decrease of the acid-tolerant group, and an increase in the lactose-fermenting group, along with the appearance of the non-lactose-fermenting organisms. The place of the *Bacillus bifidus* is now largely taken by the facultatively aerobic *Bacillus acidophilus*. The coccal forms show greater variety under this condition of diet. In children on both the breast and the bottle, a half-way stage between the two types of flora is observed. When children were fed a diet approximating more or less in type to that of adults, no one variety of organisms dominated the others as it does in the breast-fed individuals. The number of varieties present was greater. Coccal forms were numerous and very varied in type. The spore-bearing *Bacillus enteritidis sporogenes* was isolated in some cases.

These statistics emphasize very clearly the readiness with which the alimentary flora changes as the result

1. Logan, W. R.: The Intestinal Flora of Infants and Young Children, Jour. Path. and Bacteriol., 1914, xviii, 527.
2. Tissier: Compt. rend. Soc. de biol., 1899, li, 943; Ann. de l'Inst. Pasteur. 1905. xix. 109.

of relatively slight changes of diet (with its variable content of bacteria). If the simpler conditions of microbial life found in the breast-fed infant represent a great physiologic advantage, future efforts should be directed to learn how to prolong them even when the dietary regimen is necessarily altered.

Current Comment

KNOWN BY THE COMPANY IT KEEPS

The advertising manager of a certain cement company doing a national advertising business holds that, in spending his employer's advertising appropriation, it is his duty to demand of the publications he patronizes value received for the money paid. He feels that he does not get the true value when advertisements of his product are lined up with advertisements of fraudulent wares. To the advertising agencies he says:

"Will you please say to all newspapers desiring to carry our advertising that we decidedly object to being placed in close company with noisome patent-medicine ads and other fakes or near-fakes . . ."

To explain what he means, at greater length, the manager in an open letter to the Association of National Advertising Managers recalls a recent experience. Picking up a New York daily a few weeks ago, he found an advertisement unblushingly claiming that a certain "patent medicine" would cure consumption. He wrote, protesting, to the publishers of the paper who, in return, defended the advertisement and said they would continue to carry it. Commenting further on the atrocity of the claims made by the exploiter of the nostrum, the advertising manager says:

"Either this advertising doctor has a cure for consumption or he hasn't. If he is the great benefactor for which suffering humanity has looked in vain for generations, this newspaper would have a scoop and would at once give pages of free publicity. If it really believes what it aids this advertiser to say to consumptives, its editorial department is asleep at the switch."

This criticism will hold true of most "patent-medicine" advertisements. Wide-awake men in the advertising business realize that every dishonest advertisement weakens the opportunity of decent advertisers to gain the confidence of readers. Enlightened selfishness alone should impel the advertisers of meritorious and truthfully-exploited products to protest against being placed in company with swindling "patent medicine" fakers. The advertising manager just mentioned says: "Robbing consumptives or opening the door for such robbers seems to me to be business in which no decent man can engage." He might have added that the majority of schemes devoted to robbing consumptives and other sick persons would cease to exist were it not for the publicity which certain publications are willing to give them—for a consideration. The arguments and criticisms just given, while applying specifically to lay publications are applicable with equal force to medical publications. The medical profession has for years been pleading for the suppression of fraudulent advertising that directly affects the public health; at the same time our profession has tolerated and supported

medical publications whose advertising pages have been, and in many cases still are, reeking with frauds just as vicious as those to be found in newspapers that cater to quacks and "patent-medicine" fakers. The only difference between a fraudulent "proprietary" and a fraudulent "patent medicine" is in the language used in advertising the two products. A lie is no less a lie because it is told in dignified language, and a fraud is no less fraudulent because it is perpetrated on the public through the instrumentality of physicians. What the advertising manager of the cement company said with regard to advertisements in newspapers and general publications applies with equal force to advertisements in medical journals:

"Gentlemen, the time for pious prating about truth in advertising is past. The public will soon give us the laugh of scorn if we solemnly talk about truth while hundreds of mediums are brazenly sharing in the spoils of dishonorable advertising."

THE SALUTARY EFFECTS OF MUSIC

To what are the beneficent effects of music due? Darwin, who never rested until he could explain a thing, if it were explainable, could nevertheless not more explain why musical tones in a certain order and rhythm afford pleasure, than we can account for the pleasantness of certain odors and tastes. "We know that sounds, more or less melodious, are produced, during the season of courtship by many insects spiders, fishes, amphibians and birds." After all, we need go no deeper for an adequate explanation than that influences, such as music, which are agreeable, are therefore salutary, and music is agreeable because its component tones are regular, periodic vibrations, even auditory waves precisely so many to each note, being in this regard unlike noises, which are irregular, dissonant, conflicting vibrations. Sound waves impinge on the hearing sense, whence the perception is conveyed to the brain. The benignant influence of music physically is by the transmission of its influence from the cerebrum through the sympathetic system, which directs the various organs. Thus not only is music physic for the soul, dissipating mental depression, soothing psychic perturbations; but its influence may also enhance nutrition, further digestion (as by the "liver music" of the French) and restore organic equilibrium. Indeed, the entire working of the human mechanism, physical and mental alike, may be lubricated by a stream of music, which art and science should therefore have a place in the medical armamentarium. It would no doubt be too much to expect every physician to be a performer on some instrument; yet illustrious colleagues have been skilled executants. Strümpell, for example, was an excellent violinist; Billroth was a superb player on the piano, and all the better surgeon for his graceful skill on that instrument. And who among "those present" could forget how in Boston several years ago, during the reception of the American Medical Association, the glee club made up of local physicians burst forth into concerted song, to the supreme delight of their hearers? There is agitation now in behalf of music as adjuvant to anesthesia; to this end some musical

skill might be required of medical fledglings in examinations for junior internships. In any event every physician could well be at least an appreciator of music and have some understanding of that most ingratiating art.

THE ABSORPTION OF WOOD ALCOHOL THROUGH THE LUNGS

The increasing use of wood alcohol in the industries and the growing appreciation of the toxicity of the substance, involving possibilities of harm far greater than the behavior of the closely related grain spirits, ethyl alcohol, would lead one to suspect, have given the impetus to extensive physiologic investigations. To some of these, notably the experiments of Völtz and Dietrich, we have referred in the past.¹ Usually the study of the effects of methyl alcohol has been confined to conditions in which it has been introduced into the organism by way of the stomach. In some of the industries, particularly those in which denatured alcohol containing the methylated spirits are employed, the possibility of absorption of vapors of wood alcohol through the respiratory passages and lungs must be reckoned with. A very recent investigation with this point in view, by Loewy and von der Heide at the Royal Agricultural College in Berlin,² has disclosed the surprising fact that quantities of methyl alcohol as small as 0.2 per cent. in the inspired air may lead to absorption of the product into the body in not inconsiderable amounts. The absorption is slow, so that some time may elapse before the organism is "saturated" with the alcohol. Somewhat unexpected is the fact that, under comparable conditions, fat animals take up decidedly less wood alcohol exhibited as vapor admixed with air than do lean subjects. This is due to the poor solubility of methyl alcohol in fats and lipoids, a fact demonstrated by the German investigators contrary to the current beliefs of the relatively ready solubility of the lower alcohols in fats and fat-like substances.

RED AND WHITE MEAT

The irritating action of the extractives of meat during excretion by the kidneys is well known and has been the basis of a rule of treatment limiting the use of these products and the meats containing them to a minimum in the treatment of parenchymatous and interstitial nephritis. Because certain red meats contained a large amount of extractives, the rule to exclude red meats and permit white meats and fish gained currency. More recently it has been shown that some white meats contain a high percentage of extractives, so that the chemical composition of the two varieties of meat does not differ sufficiently to justify a marked preference for the white meat over the red. On the other hand, there are those who still assert that the objection to red meats as opposed to white is well founded. Thus McCrae in Osler's

"Modern Medicine"¹ says "All kinds of meats contain extractives, and the so-called dark meats to a greater extent than the light meats. Adler," McCrae says, "in a review of the subject, concludes that the prevalent idea that the subject of renal disease ought to eat light rather than dark meats is correct, and that these meats boiled contain the harmful factors less than when roasted." The fact is that the color is an insufficient criterion. The objection to extractives as irritating to the kidneys is quite correct and the important point is to determine for each kind of meat whether it contains a sufficient amount of the extractives to be injurious. The question thus seems to be reopened. Kindborg,² in the chapter of his text-book dealing with this subject, concludes that the old distinction between red and white meats cannot be sustained. He finds his recommendations for the use of meat in nephritis on the comparative amount of extractives in the individual sorts of animal food. Thus some sorts of fish are higher in extractives than most kinds of meat and their effect on the kidneys must be judged accordingly.

Medical News

ARKANSAS

Personal.—Dr. Walter K. Grey has been appointed local surgeon for the Iron Mountain System at Cotter.—Dr. William C. Tipton, Mountain Home, has been appointed physician in charge of the Confederate Soldiers' Home, Little Rock.

Home from Abroad.—Dr. and Mrs. James H. Buckley, Fort Smith, returned from Europe, August 12.—Dr. Ollie W. Clark, Pine Bluff, reached home from abroad, August 20.—Dr. R. Manton Wilson, Hope, who has been in Korea for eight years as a medical missionary, has returned home.

ILLINOIS

Personal.—Dr. Albert F. Storke, for five years president of the Board of Health of Oak Park, has resigned.—Dr. Clara Harrison Towne, Lincoln, has resigned as psychologist at the Lincoln State School and Colony.

Home from Abroad.—Dr. and Mrs. Robert S. Denney, Aurora; Dr. and Mrs. Karl F. Snyder, Freeport; Dr. Nina P. Merritt, Alton; Dr. Frederick E. Roberg, Joliet; Dr. George B. Kelso, Bloomington, and Dr. Ora L. Pelton and family, Elgin, have returned from abroad.

Chicago

Changes Field of Labor.—Dr. Thomas H. Glenn, formerly in charge of the pathologic and bacteriologic laboratories of the Northwestern University, has been placed in charge of the clinical and Roentgen-ray laboratories now being installed in the First National Bank Building, Fort Dodge.

Abroad and Home from Abroad.—Dr. Carl Langer and family and Dr. and Mrs. Bradford A. Camfield have returned from abroad.—Dr. and Mrs. Zenas H. Going are reported to be in London.—Dr. Anthony Biankini, Dr. Walter K. Allport, Dr. and Mrs. Alfred Schirmer and Dr. Hayden S. Barnard and family are still in Europe.

INDIANA

Reappointments on State Board.—The governor has reappointed Drs. Moses S. Canfield, Frankfort, and W. A. Spurgeon, Muncie, as members of the State Board of Medical Registration and Examination.

Indiana Physicians Returned and Abroad.—Dr. Malachi R. Combs, Terre Haute, has landed in New York.—Dr. and Mrs. Charles O. Bechtol, Marion, have reached home from Germany.—Dr. Manford M. Clapper, Hartford City, who had been marooned in London, has reached home.—Dr. and Mrs. Edward F. Hodges, Indianapolis, are said to be in London.

2. Loewy, A., and von der Heide, R.: Ueber die Aufnahme des Methylalkohols durch die Atmung, *Biochem. Ztschr.*, 1914, lxxv, 230.

1. Osler: McCrae in *Modern Medicine*, Ed. 2, iii, 784.
2. Kindborg, E.: *Innere Medizin*, iii, 90.

KENTUCKY

Personal.—Dr. B. Frank Eckman, Covington, has returned from Europe.—Dr. and Mrs. Frank T. Fort, Louisville, have returned from abroad.—Dr. W. Edward Grant, health officer of Louisville, who has been ill for four months, is convalescent and has resumed practice.

MARYLAND

Abroad.—Dr. H. Flournoy, resident psychiatrist at the Henry Phipps Psychiatric Clinic of Johns Hopkins Hospital, and a member of the medical reserves of the Swiss army, has left Baltimore to return to Switzerland, in answer to his country's call for reservists.—Dr. Ernest Zuehlín, who is in Germany, has not been heard from and it is thought that he will remain in his country and assist in the army or in some hospital that will be established for the wounded.

Personal.—Dr. Robert F. Wells, Gamber, is ill with typhoid fever in St. Anthony's Hospital, Baltimore.—Dr. Charles R. Edwards, Baltimore, who was operated on for appendicitis, has recovered and resumed his practice in the University Hospital.—Dr. Thomas Boyle Owings is said to be critically ill at his home, Owings Glenn, Ellicott City.—Dr. Francis E. Harrington, Cumberland, has been appointed assistant epidemiologist in connection with the United States Public Health Service, Washington.

Home from Abroad.—Dr. Charles E. Hartwig of Baltimore who arrived on the refugee ship *Princesa Mafalda* from Europe tells of his capture by the Austrians as a spy. He was searched and questioned and turned over to the police of Vigi di Fassa. Eventually he proved his American citizenship and was released.—Physicians who have returned from Europe are Dr. Joseph Bloodgood, Dr. Frank Martin, Dr. Randolph Winslow and Dr. Frederick Baetjer; Dr. James T. Johnson, Cumberland; Dr. and Mrs. Alexander D. McConachie and Dr. Mary N. Browne, Baltimore.

MISSISSIPPI

Personal.—Dr. Edward C. Parker, Gulfport, has returned from abroad.—Dr. Thomas O. Hunter, Biloxi, registrar of the statistical department of the State Board of Health, is said to have been removed by Dr. Ethelbert H. Galloway, Jackson, secretary and executive of the board.

Progress of Hookworm Campaign.—The work in Jones County was brought to a very successful conclusion toward the end of August, over 2,500 cases having been treated. Hookworm was found in over 60 per cent. of all cases examined, the largest percentage being found in children. The people showed much interest and cooperated in the work. Many schools were found in which all the teachers and pupils were infected. Much infection in country schools is attributed to the ingestion of the eggs of the parasites in drinking-water obtained from springs near the schools.

MISSOURI

New Sanatorium.—Dr. W. S. Woodford, West Plains, has leased the Havens property in Carthage which was formerly used by Dr. Fulton as a sanatorium and will equip it and operate it as Woodford's Sanitarium. The institution will be opened some time next month.

Poison Selling Restricted.—An ordinance has been adopted by the city council of Joplin, placing restriction on the sale of morphin, cocaine, heroin, carbolic acid and other poisons and also on the extracts and derivatives of habit-forming drugs. The ordinance also prohibits the distribution of sample packages or bottles of medicine.

Missourians Abroad.—Dr. and Mrs. Charles C. Dennie and Dr. and Mrs. Edward G. Blair, Kansas City; Dr. William F. Schmid, St. Joseph, and Dr. and Mrs. John J. Bourn, Hannibal, have returned from abroad.—Dr. Andrew L. Shog, Kansas City, is said to have been placed in charge of the Salpêtrière Hospital, Paris.—Dr. James W. Heddens and family, St. Joseph, are in Stratford-on-Avon, England.—Dr. J. Elliott Royer, Kansas City, is in a hospital in Bern, Switzerland, recovering from injuries received in a fall while mountain climbing.

St. Louis

Personal.—Dr. Wilhelmina A. Ragland is interned in Switzerland.—Drs. Christopher C. Morris and Walter R. Hewitt have returned from abroad.

Banquet to Hospital Board.—Hospital commissioner, Dr. Cleveland H. Shutt, and the hospital superintendents gave

a dinner in honor of the members of the hospital board, August 29.

Leper Escapes from Colony.—George Rusuls, a Greek, who has been under the observation of the health authorities for leprosy and was sent to join the leper colony at Quarantine, August 29, escaped a few hours later.

Hospital Opened.—The three-story building at Grand Avenue and Palm Street, recently purchased for \$30,000 by the board of benevolence of the Christian Church, which has undergone extensive alterations and decorations, will be opened in a short time as the Christian Hospital. The institution has a capacity of fifty beds, and the officers of the staff are, Dr. Julius C. Heinrichs, president; Dr. Albert E. Meisenbach, vice-president, and Dr. Treston R. Ayars, secretary-treasurer.

MONTANA

Personal.—Dr. Fred F. Attix, Lewistown, has returned from abroad.—Dr. Robert I. Rizer and family, Anaconda, believed to be in Vienna.—Dr. Charles R. Blake, Butte, and Harry A. Bond, Dillon, have entered into partnership.

Prosecution of Milk Dealers.—The first prosecution of milk dealers in Cascade County was conducted July 17, at Great Falls, when the proprietors of five local eating houses were tried in the justice court for selling milk containing less than the standard percentage of butter fat. Three of the restaurant proprietors were tried and found guilty, and two pleaded guilty without the cases coming to trial.

NEW YORK

Personal.—Dr. Baxter T. Smelzer, Albany, has returned from abroad.—Drs. Thomas A. Ryan and Edward G. Griffin have been appointed examining physicians for the Albany District by the State Compensation Commission.

Wants Psychopathic Ward.—In a report made to the health commissioner of Buffalo by Dr. Baron Ross Nairn, examiner in lunacy, an appeal is made for a better psychopathic ward for the care of Buffalo patients under observation for supposed lunacy.

Children's Haven Opened.—On August 29 the Children's Haven at Far Rockaway was formally opened by Health Commissioner Goldwater. This home has accommodations for thirty-five and will care for children whose widowed mothers are in hospitals.

New York City

Personal.—Drs. John W. Draper, William J. Robinson and wife and George W. Jean have returned from abroad.—Dr. Lewis S. Pilcher, Brooklyn, has been elected surgeon-general of the Grand Army of the Republic.—Dr. Moses S. Kakels, Dr. Sara Welt-Kakels, Dr. John Warren and Dr. M. E. Rhein have returned from Europe.

NORTH CAROLINA

Home from Europe.—Drs. Lucius N. Glenn, Gastonia and Jacob F. Highsmith and daughter, Fayetteville, have returned from abroad.

Field Hospital Encamped.—Field Hospital, No. 1, N. C. N. G., encamped the last week in August at Camp Battle near Hendersonville. More than one hundred members were present.

Antityphoid Vaccination.—The North Carolina State Board of Health is now furnishing antityphoid vaccine, and in Robinson County alone more than 2,800 inoculations have been made.

Health Seekers Society Chartered.—The Asheville Health Seekers Society has been incorporated without capital by D. A. Pressley, W. P. Harvey and James Williams, with the object of providing friendly attention for worthy tuberculosis patients, funds for their needs and a sanatorium for the care of patients with small means and those who are indigent.

Personal.—Dr. J. Vance McGougan, Fayetteville, gave his annual entertainment to the Cumberland and Hoke Counties Medical Society, August 20, at his country place.—Dr. James M. Covington, Wadesboro, has been added to the state hookworm commission.—Dr. Samuel W. Hurdle, Reidsville, has been appointed whole-time health officer of Rockingham County, vice Dr. Samuel Ellington, Wentworth, resigned.

OKLAHOMA

Personal.—Dr. Charles R. Preston, Mountain Park, lost his office furnishings by fire, recently.—Dr. George W.

Sutton, Cleveland, has purchased the Bartlesville Hospital and has remodeled it and increased its capacity to twenty-five beds.—Dr. Alva A. West, Guthrie, will remain in England during September.

The Tables Turned.—Dr. G. Fowler Border, Mangum, was recently made the object of an unusual attack. It is alleged that an attempt was made by two women to induce him to perform a criminal operation, a dictograph having been placed in the room before the conference. Dr. Border, instead of being trapped, trapped the trappers. Two arrests have been made and Dr. Border is said to have filed suit for \$100,000 against the Burns Detective Agency, Chicago.

PENNSYLVANIA

Personal.—Dr. Henry J. Benz has succeeded Dr. Henry B. Burns as superintendent of the Bureau of Child Welfare of Pittsburgh.

Physicians Entertained.—The Carbon County Medical Society was entertained by Dr. John W. Luther, Palmerton, at a clam bake and cornroast recently, at Lake Mineola near Brodheadsville.

Home from Europe.—Dr. Martin E. Griffith, Monessen; Dr. and Mrs. George B. Kunkel and son, Harrisburg, and Dr. Charles H. Schlesman and son, Allentown, have returned from Europe.—Dr. Tyrus E. Swan, Easton, has reached London on his return home.

Bulletin on Health of Schoolchildren.—Dr. Samuel G. Dixon, state health commissioner, issued his thirty-first *Weekly Bulletin*, August 30. It deals with the health of schoolchildren and the care and attention which should be paid to them before entering the school that much illness from contagious diseases may be prevented.

Philadelphia

Personal.—Dr. Charles B. Penrose arrived from Europe September 3.—Dr. Howard F. Hansell arrived in New York September 2.—Dr. James William White is taking a trip through the Puget Sound Country and British Colony.—Dr. Walter L. Pyle has returned after a trip to Demerara, British Guiana.—Dr. Karl Schaeffle has succeeded Dr. Edward B. Shellenberger, Harrisburg, as deputy medical inspector of tuberculosis dispensaries.

Million Assured for Blockley.—It has been announced that Councils' Finance Committee will yield to the demand of the physicians that the next loan shall include \$1,000,000 to start the reconstruction of the Philadelphia General Hospital. While the overcrowding has been relieved to considerable extent by the removal to Norristown of many of the insane and indigent patients, and by other arrangements, there is still insufficient room at Blockley and, what is worse, it is impossible to give modern treatment in accordance with advanced ideas of sanitation in the present old buildings.

Rat Receiving Station.—On September 4, a rat receiving station was installed at the Race Street Pier and the payment of bounties for live and dead rats began. William J. Wahl, an inspector of the Board of Health, is in charge of the station, which is open from 8 a. m. to 5 p. m. and is connected by telephone with the electrical bureau. Thirty rats taken from the liner *Merion* which docked from Liverpool, have been taken to the city laboratories to be examined for traces of bubonic plague. Rats are being taken from the holds of all vessels docking at this port, as a part of the campaign instituted by Director Harte of the department of health and charities. A corps of nearly a score of special agents is inspecting vessels as they arrive, and also is collecting rats from several hundred traps placed along the Delaware River front between Girard Avenue and Reed Street. It is hoped in this way to keep out the bubonic plague.

TENNESSEE

Hookworm in James County.—Dr. Yancey, state hookworm examiner, after an investigation in James County, declared it heavily infected with hookworm. Of about 100 children examined, 75 were found infected.

From, to and in Europe.—Drs. Herbert T. Brooks and Otis S. Warr, Memphis; Drs. George Manning Ellis, Edwin Dunbar Newell, German P. Haymore, Henry Berlin, James H. Atlee, James A. Smith and John S. B. Woolford, Chattanooga; Drs. Albert G. Kern, Knoxville, and Albert W. Harris, Nashville, have returned from Europe.—Drs. Cary Snoddy and Robert H. Newman, Knoxville, sailed on the

hospital ship, *The Red Cross*, September 9.—Dr. Hiram B. Jacobsohn has reached Rotterdam from Vienna on his way home.

TEXAS

South Texas Physicians to Meet.—The annual meeting of the South Texas Medical Society will be held in Corpus Christi, September 15 and 16, under the presidency of Dr. F. W. Painter.

Health Exhibit Car.—The appropriation of \$10,000 made by the thirty-third legislature is sufficient to equip and maintain a health exhibit car which will start on its journal over the state this month. The car will be accompanied by a director and a corps of lecturers and demonstrators.

Physicians Abroad.—Drs. Edward H. Cary and Garfield M. Hackler, Dallas; Otto K. Peters, Galveston; Samuel P. Cunningham, San Antonio, and Joseph Gilbert, Austin, have returned from abroad.—Dr. James W. Ward, Detroit, is believed to be in Vienna.—Dr. and Mrs. Harold L. Warwick, Fort Worth, are in London.

Personal.—Dr. Edmond Doak, heretofore associated with the Taylor Sanitarium, has purchased a third interest in the Taylor City Hospital.—The Whiteside Office Building, owned by Drs. E. F. and M. A. Whiteside, Timpson, was burned August 6, with a loss to Drs. Whiteside of \$2,000 in office books and instruments, and of \$1,500 to Dr. Ollie F. Johnson.

GENERAL

Colored Physicians Meet.—The National Medical Association held its annual meeting in Raleigh, N. C., August 25 to 27 and elected the following officers: president, Dr. Frank S. Hargrave, Wilson, N. C.; vice-presidents, R. C. Brown, D.D.S., Richmond, Va., and W. A. Jones, Ph.G.; secretary, Dr. Walter G. Alexander, Orange, N. J.; assistant secretary, Dr. G. R. Ferguson, Charleston, S. C.; treasurer, Dr. J. R. Levy, Florence, S. C. It was decided to meet in Chicago in 1915.

Hospital Chiefs Confer.—At the sixteenth annual meeting of the American Hospital Association held in St. Paul, August 24 to 28, the followings officers were elected: president, Dr. William O. Mann, Boston, superintendent of the Boston Homeopathic Hospital; vice-president, Dr. Arthur B. Ancker, superintendent of the St. Paul City Hospital; W. W. Kenney, superintendent of the Victoria General Hospital, Halifax, N. C., and Miss Ida N. Barrett, superintendent of the Grand Rapids (Mich.) Hospital; secretary, Dr. Harry A. Boyce, superintendent of Kingston General Hospital, Kingston, Ont., reelected, and treasurer, Asa Bacon, superintendent of the Presbyterian Hospital, Chicago, reelected. It was decided to hold the next meeting of the association in San Francisco.

Prevention of Tuberculous Infection in Children.—The trustees of hospitals for consumption for Massachusetts have sent a circular letter to physicians of that state calling attention to the responsibility resting on the profession in the prevention of consumption, especially among children. The trustees suggest that it is tuberculous children who cannot stand the strain of young adult life that furnish our thousands of new cases of pulmonary tuberculosis each year. It is the opportunity of physicians, first to protect these children from infection, and second, to see that they are cared for when such infection has taken place. When actual disease is evident the case has probably gone beyond the stage when cure is possible. A diagnosis of "infection" as contrasted with a diagnosis of "disease" is the key to this problem. Physicians are requested to aid by reporting these cases, simply as a matter of record, to the State Board of Health, which will furnish special cards for the purpose.

The Plague in New Orleans.—Since the report of bubonic plague in the last issue of THE JOURNAL, three cases of human plague and eleven cases of rodent plague have been discovered. The human cases are as follows: Case 23, Max Neuman, white, male, nativity, United States; residence, 421 Harmony Street; employed at grocery store, corner Carrollton Avenue and Green Street; aged 19; sickened, August 29, with left femoral bubo. Case 24, Ethel Ticker, white, female, residence, 1742 Touro Street, corner Roman Street; sickened September 1, diagnosis positive September 2, with left femoral bubo. Case 25, Lloyd Wilson, white, male, occupation, plumber; residence, 1824 Baronne Street; sickened September 1, suspicious September 2, diagnosis positive September 3, left femoral bubo. Cases 75 to 85, inclusive, of rodent plague have also been found. During the week ended August 29, in the Department of Outgoing Quarantine, 81

vessels were fumigated with sulphur; 15 with carbon monoxide; 9,764 pounds of sulphur were burned; 15,736 tons of outgoing freight were inspected and 32 clean and 6 foul bills of health were issued. The Overland Freight Inspection Department inspected 3,925 cars; rat-proofed 1,230 cars, and condemned 9 cars. No rodents were killed in cars during the week. In the Department of Field Operations, 9,178 rats were trapped, 4 premises were fumigated, 40 premises were disinfected, 3,726 premises were inspected, 150,008 poisons were placed, 1,926 notices were served, 117 buildings were rat-proofed, 774 abatements were made and 121 dead were inspected. In the Department of Laboratory Operations, 8,235 rodents were received, of which 6,614 were examined, 18 were found suspicious and the diagnosis of plague was confirmed in 14. The total number of rodents trapped thus far is 64,063 and of these 58,599 have been examined.

CANADA

Medical Corps Organization.—Previous to 1899 there was no Army Medical Corps in Canada, each regiment having its own medical officers. At the present there is an organized system of 700 medical officers and 1,800 non-commissioned officers and men. Sir Ian Hamilton recently reported that the medical corps keeps well ahead of every other branch of the military service in its completeness and preparations for war.

Personal.—Dr. Max Klotz, Ottawa, immediate past president of the Ontario Medical Council, who has been doing graduate work in Germany, has arrived in England and will sail for home immediately.—Dr. George Strathy, Toronto, has returned from England.—Dr. Walter Wright, Toronto, is now doing work in Moorfields, London, England.—Dr. D. W. McPherson, Toronto, left the past week for Valcartier Camp near Quebec, in charge of the Army Medical Corps, Toronto. Dr. Wallace Scott was second in command.—Dr. D. A. Clark, Toronto, has gone with his regiment to the camp.—Dr. S. P. Ford, Norwood, Ontario, who has practiced in that village for fifty years, was recently tendered a banquet and a congratulatory address by the physicians of Peterboro and surrounding country.—Dr. G. G. Nasmith, bacteriologist to the Toronto Board of Health, is at Camp Valcartier watching the water supply.—Dr. George R. McDonagh has returned to Toronto from England.—Dr. William Burt, Paris, Ont., Drs. Charles J. Hastings, Herbert J. Hamilton and Augusta Stowe Gullen, Toronto, have been reelected to represent the graduates in medicine on the senate of the University of Toronto.—Dr. A. T. Shillington, Ottawa, is in charge of the medical services at Camp Valcartier. He states that out of a total of 33,000 in camp, but fifty-one have developed any illness.

WAR NOTES

Russia Organizing a Corps for Cholera Service.—The Russian authorities are considering a proposal to establish a corps for cholera service to consist of 10 medical men and 20 nurses.

Medical Service in England.—As many practitioners and panel physicians have taken places in military service, arrangements are being made to fill their places temporarily and conserve their practices during their absence.

Foreign Medical Publications.—Recent issues of foreign medical publications are exceedingly thinner in bulk and especially in original contributions. The issue of the *Lancet* for August 29 is the annual Students' Number and contains no original articles. Much space is given in current British journals to war news.

England to Manufacture Synthetic Drugs.—Agitation is being made for English chemical companies to arrange for the manufacture of German synthetic products. Duty free alcohol is being urged to aid manufacturers in this work. The patent laws are such that firms who will undertake to manufacture the necessary products at this time may continue to do so even after peace is declared. Edward White, president of the British Pharmaceutical Society, has recommended that sodium salts be substituted for potassium, as Germany is the great source of the latter.

Compulsory Antityphoid Vaccination of English Army Urged.—Sir W. B. Leishman has published a letter urging compulsory antityphoid vaccination for the British army and pointing to the American success during the mobilization in Texas. As it is impossible to vaccinate all the recruits en masse, Lord Kitchener has expressed a wish that all may be vaccinated as rapidly as occasion offers. Antityphoid vac-

cine is supplied on requisition from the Base Depot of Medical Stores, and medical officers are urged to seize every opportunity to increase the number of the inoculated.

Switzerland Appeals for Aid.—The Official Information Bureau of Switzerland, located in New York, writes that the Swiss Republic has been compelled to call to arms the entire Swiss army of 300,000 men, in order to be prepared to enforce and defend the neutrality of the country. This leaves the harvests to be gathered by the aged and by women and children, and imposes a heavy burden on the 3,500,000 population, more particularly as the customary trades and industries of the country are at a standstill. An appeal is made to Americans for contributions to meet the needs of the destitute; these may be sent to the Swiss Relief Fund, 241 Fifth Avenue, New York.

Surgical Scissors and Forceps.—Few physicians realize that all, or nearly all, surgical scissors and forceps are imported, most of them from Germany. The war, of course, has closed practically all the surgical instrument factories. A correspondent who is interested in the subject, and who has just returned from abroad, writes: "While I was in Europe I saw factory after factory where the first call took out from 60 to 85 per cent. of the men. There is no doubt but that the instrument business of this country will be in bad shape inside of the next sixty days." This means that it will stimulate and encourage our home instrument-makers to undertake the manufacture of these instruments.

Pharmaceutical Arrangements in Austria.—The Austrian Department of the Interior has issued an order requiring the public pharmacies to be kept open as far as possible. In case the proprietor or the responsible manager of the pharmacy is compelled to be absent for military service, a master of pharmacy can be entrusted with the conduct of the pharmacy without the requirement of a definite period of professional service. The order also provides that in cases in which a master of pharmacy cannot be obtained, and there is an urgent necessity for a public place for the furnishing of medicines, a medical house pharmacy can be established. The order further provides that in such cases a sign, giving the residence of the physician conducting the pharmacy, shall be distinctly displayed to the public and similarly in the case of pharmacies whose business must be suspended, a sign indicating the nearest accessible pharmacy must be displayed.

Conditions of Life in Paris.—Three weeks after the mobilization, as noted by a special correspondent to the *London Lancet*, the greatest change in Paris was in the traffic arrangements. All buses have ceased operations and the city is much more quiet. All horses and private motor cars were commandeered. The street railway ceased operations except from 7:30 a. m. to 7:30 p. m. and the wives of the employees took their places. Food conditions generally are fair and arrangements are being made to conserve the food supply. Notices have been posted urging all who have not been vaccinated in the last five years to apply at any of the hospitals or the vaccination bureaus which have been established. Directors of primary schools and medical inspectors have been instructed to vaccinate all children. Among other sanitary measures, burning of all rubbish and boiling of water have been urged. No wounded soldiers are sent to Paris for the present; they are being sent to the provinces.

Red Cross Expedition Sails.—The American National Red Cross steamer, *Red Cross*, formerly the Hamburg-American steamer, *Hamburg*, was still at New York September 9, having on board ten hospital units to assist in the care of the wounded in the European armies. Major Robert U. Patterson, M. C., U. S. Army, is in command of the detachment and the officers of the units are as follows: (1) Dr. Reynold M. Kirby-Smith, Sewanee, Tenn., director; Drs. John A. C. Colston and Martellus H. Todd, Baltimore, assistants; (2) Dr. Roades Fayerweather, Baltimore, director; Drs. Lewis C. Spencer and Harry Richmond Slack, Baltimore, assistants; (3) Dr. William S. Magill, New York City, director; Drs. Philip Newton, Washington, D. C., and Paul H. Zinkhan, Salem, Ore., assistants; (4) Dr. Robert W. Higgs, Buffalo, N. Y., director; Drs. Fred W. Eastman and Henry N. Shaw, assistants; (5) Dr. Edward H. Egbert, Washington, D. C. director; Drs. Brown S. McClintic, Peru, Ind., and Arthur M. Zinkhan, Washington, D. C., assistants; (6) Dr. Charles H. Sanders, Washington, D. C., director; Drs. John S. Spearman, Baltimore, and Grover A. C. Stem, Washington, D. C., assistants; (7) Dr. Cary A. Snoddy, Knoxville, Tenn., director; Drs. Fred G. Benton, New York City, and Walcott Denison, St. Louis, assistants;

(8) Dr. John D. Bartlett, Galesburg, Ill., director, Drs. Russell A. Jewitt, Cleveland, and John C. Miller, Shenandoah, Pa., assistants; (9) Dr. Howard W. Beal, Worcester, Mass., director; Drs. Veader N. Leonard, Baltimore, and William T. Fitzsimons, New York, assistants; (10) Lieut. Col. Bial F. Bradbury, M.C. Maine N.G., Norway, director; Drs. Robert H. Newman, Knoxville, Tenn., and John Lancer, New York, assistants. Its sailing was delayed because of protest from foreign consuls regarding the large number of Germans, not American citizens, on the crew.

Shortage of Medical Supplies in Austria.—The influence of the war on the market for drugs is felt not only in this country but even in Austria although she is an ally of Germany in which so large a part of the drugs used is manufactured. As will be seen from another item, the German Emperor has forbidden the exportation of a large number of very important drugs. The "Pharmaceutische Post" for August 8, calls attention to the effect of this law on the drug market in Austria and to the unfortunate position which a nation is in when it has to depend on other nations for its important drugs. Most chemical preparations, among them the most important alkaloids like morphin, the analgesics and hypnotics, are not produced in Austria but only in Germany, and at present cannot be imported on account of the necessities of the war.

This situation affects not only public pharmacies, but also the public hospitals and even the military hospitals which must supply their needs through the wholesale druggists. A circular from the latter has already been sent to pharmacists in which they have set forth the serious economic condition that has been called into being by the war and demand attention to these conditions on the part of pharmacists. They also make the announcement that they will furnish goods only for cash and are compelled to make an advance of 15 per cent. on all goods. Some makers of bandage material have raised the prices in their list from 40 to 80 per cent. Under such circumstances it is impossible that pharmacists shall maintain the price of medicines established by law, and permission must be given them, according to the Post, to make on their part, a corresponding increase in their charges.

The standing committee of the Vienna Medical Chamber and of the Economic Organization of Physicians of Vienna has also addressed a public request to the Vienna physicians to prescribe imported alkaloids only in the amounts absolutely necessary.

Exportation of Medical Supplies from Germany Forbidden.—In its current issue the *Pharmaceutical Post* published in Vienna, quotes from the *Berlin Drug News* the following order issued by the kaiser:

We, William, by the grace of God, German Emperor, King of Prussia, etc., in the name of the Empire, with the complete concurrence of the Bundesrat, issue the following orders:

1. The export and transport across the boundaries of the German Empire of material for dressings and remedies, as well as surgical instruments and apparatus, is forbidden until further notice.

2. The Imperial Chancellor will publish a list of articles whose export and transportation is forbidden according to Section 1. He is empowered to permit exceptions to conditions in 1 and to establish necessary regulations.

3. The present order is to take effect on the day of its announcement (publication).

In witness whereof, behold our Imperial signature and the impression of the Imperial seal.

Given at the New Palace, July 31, 1914.

(L. S.) WILHELM,
VON BETHMAN HOLLWEG.

In connection with the above, the following announcement is published:

On the basis of the second paragraph of the Imperial orders of July 31, 1914, regarding the prohibition of the export and transportation of dressing material, remedies and surgical instruments and apparatus, I make public announcement that the following articles come under this prohibition: Pure carbolic acid, mercury, corrosive sublimate, iodine, potassium iodide and sodium iodide, iodoform, chloroform, pyrazolonum phenyldimethylcum (antipyrin) and its derivatives (pyramidon, etc.), powdered opium, morphin and its salts, codein phosphate, paraformaldehyd, quinin hydrochlorid and sulphate, arecolin, salvarsan, absorbant cotton, gauze for dressings and other dressing material, surgical and other medical and dental instruments and apparatus, bacteriologic apparatus, material for bacteriologic media (agar, gelatin, peptone), vaccine virus, prophylactic sera and curative sera for infectious diseases and also experimental animals.

Berlin, July 31, 1914.

I. V. DELBRÜCK,
Imperial Chancellor.

On September 8, Representative Metz reported the raising of the export embargo on dyestuffs via Rotterdam, including medicinal products with the exception of chloroform, carbolic acid, serums and salvarsan.

LONDON LETTER

LONDON, Aug. 14, 1914.

Libel Action Against the British Medical Association

A nostrum proprietor named Stevens has brought an action against the British Medical Association for statements made in "Secret Remedies," the book in which the association has exposed various quacks. It may be remembered that last year this individual, who professes to cure consumption, brought an action in which the jury disagreed. In the present case he appeared in person. In addressing the jury he claimed that he had discovered a cure for consumption which had proved successful in his case when sent to South Africa seventeen years ago by his family doctor. In the association's book it is stated that "the vendor considerably warns the public against American quacks and impostors," but though so engagingly candid about his rivals he follows the plan of sending one letter after another to any sufferer whose name he may have obtained, a system which seems to have been invented in America. His circulars have a character of their own, because of his effrontery to the medical profession. Persons who respond receive a list of questions to be answered by their doctor and are advised to continue under his observation that he may be impressed by the marvelous qualities of the remedy. He also said, "The great drawback to my cure so far as the medical profession is concerned has been the fact that I would not reveal its formula. This is now done away with. The formula is 80 grains of umckaloabo root and 13 grains of chijitje to every ounce prepared according to British Pharmacopeia methods." The book commented on "the farce of revealing a formula by the employment of such fancy names as one of the oldest dodges of the quack medicine man." The following analysis was given: "The medicine contained in 100 fluid parts 21.3 alcohol, 1.8 glycerin and 4 solid substance; the latter contained about 1 part of tannin and 0.2 of ash. The solid substance agreed in all respects with the solids of decoction of krameria." In his advertisements Stevens guaranteed to cure the patients or to return the money in full. He also alleged that he returned to England to prove his cure to the satisfaction of the British government.

For the association evidence was produced that a man who went to see Stevens concerning some clerks in the same employ said he was subject to colds in the head. Stevens volunteered to examine him and said that his left lung was in a bad condition and gave him an injection. He subsequently saw a chest specialist who found there was nothing the matter with him. Dr. Bullock, a pathologist, said that he experimented with Stevens' remedy and found that it had no bactericidal properties, although the claim was made that a dilution of 1:100 killed tubercle bacilli. Sir Richard Douglas Powell, former president of the Royal College of Physicians, stated that he knew no remedy which would cure consumption. A physician from West Africa gave evidence on behalf of Stevens. He had heard the name "umckaloabo." It was a Kafir word meaning "life everlasting" and was applied to a plant in Kafir Land; a decoction made from it contained a vegetable parasite which was an antitoxin for chest complaints. Stevens produced several witnesses who stated that they had been cured of consumption by him. Well-known specialists gave evidence that there was no proof that these persons had suffered from consumption. It was also shown that although Stevens issued guarantee bonds promising to refund the money if a cure was not accomplished, yet when his patients died and their families, who were in poor circumstances, applied for the return of the money, he refused to give it. The jury returned a verdict in favor of the defendants. The British Medical Association is therefore to be congratulated on its successful exposure of this quack.

Jews and Consumption

It is generally held that Jews are much less liable to tuberculosis than other white races. That this view requires some qualification seems to be shown by Dr. D. L. Thomas, Health Officer for Stepney, a district in the East End of London mainly inhabited by Jews. He holds that consumption is more common among Jews than other classes and that it is undoubtedly on the increase among them. The return of cases notified and the number of deaths in certain model dwellings occupied by 5,789 Jews and 6,848 Gentiles, showed that in the buildings entirely occupied by Jews, 95 notifications were received, and there were 14 deaths or 14.7 per cent. of the persons attacked. In the buildings where there were no Jews, 26 notifications were received and there were 6

deaths, a percentage of 23 of those attacked. So that a greater percentage of Jews than of Gentiles contracted the disease, but a smaller percentage of those attacked died. These figures, adds Dr. Thomas, "tend to confirm the opinion I have frequently expressed, that pulmonary tuberculosis is more common among Jews than others and that it appears to be of a more chronic nature. Its chronic character may be the cause of its greater prevalence among Jews. Some of these chronic patients live for many years. They cough and expectorate quantities of sputum laden with tubercle bacilli, and are the center of infection for many years. The danger of this in crowded rooms or in workshops where many work in close proximity to each other, is obvious." In regard to the above statistics it must be borne in mind that the Jews in Stepney are among the poorest and most down-trodden of their race. Driven by oppression out of Russia they seek refuge in England, where they overcrowd certain slums and begin the struggle for existence at a disadvantage.

BERLIN LETTER

(Delayed in transmission)

BERLIN, Aug. 8, 1914.

The War

Although we have been prepared for years for an attack from Russia, France or England, the gigantic war in which we are now involved quite unexpectedly has naturally affected German physicians severely. In an economic way it bears on the entire profession, especially on those liable to military service by the call to service in the army. Aside from the army surgeons belonging to the standing army, the surgeons who are on furlough (reservists) were immediately mobilized. In addition, a large number of physicians in civil life who, in part, are no longer bound to military service, and in part have never performed it, have placed themselves at the disposal of the war department mostly, for hospitals which will later be erected in their own home towns. It is at present not possible to determine the number of physicians who have gone into active service, but if one estimates from comparison with the conditions in the Franco-Prussian war of 1870-1871, there would be about 12,000 physicians in the army. Naturally the question arises, How will the civil population receive medical care in the absence of so large a number of physicians? The representatives of the medical profession made immediate provision for active help in this matter. The Medical Chamber of Berlin-Brandenburg has required all the physicians of its district who are in the position to do so to assume without charge the practice of their colleagues who are in the field, and among the physicians who have already given notice of their willingness to serve in this way a representative service has already been organized. It is distinctly provided that the substitute shall fully assure the income to his colleague serving in the army or to his family. Similar measures will doubtless be taken in other parts of Germany. The task of providing that the families of physicians who are deprived of their support through service in the army shall receive material aid so far as possible is of especial importance. Also in this respect the Medical Chamber of Berlin-Brandenburg has already taken steps to the extent that the loan committee has announced that it will allow loans to the needy families without interest so far as its means permit. In the *Deutsche medizinische Wochenschrift*, it is further stated that the great fund of the League of insurance societies and which is no longer of value for its original purpose, is to be devoted, as far as possible, to the members and their families. If these and similar measures of the authorities of the profession are insufficient to provide the needed assistance, there is no doubt that physicians of the profession who remain at home will provide funds for the welfare of the profession.

The great enthusiasm which prevails among the German people expresses itself not only in the readiness to go to war, but also in the willingness for sacrifice which is necessary to provide means for the care of the wounded. Already in the first days of mobilization, a fund was provided of about \$250,000 (1,000,000 marks) by some banks and private individuals, to which the kaiser alone contributed from his private purse \$25,000 (100,000 marks). The offer of the American Red-Cross to send an expedition of three surgeons and twelve nurses with the necessary material to care for our wounded, communicated by the American government through its ambassador, has been received with marked appreciation. The resolution of the members of the Society

of American Physicians of Berlin to offer their services to the German army has been received with no less favor. Naturally, the military hospitals are of the first importance for the reception of the wounded. Next come the state and municipal hospitals which, in consideration of the enormous size of the army and the extent of the individual battles, must soon be made use of. Moreover, physicians have already offered their private clinics for this purpose. Further, some of the nobility have arranged to care for the wounded in their castles. The Kaiser Wilhelm Academy of Berlin for the instruction of army surgeons is arranged for the care of convalescents. Its doors are naturally closed to students, for the younger students have been sent into the army as nurses, and the oldest have taken an emergency medical examination and gone with the troops as assistant surgeons. Moreover, their studies have been permitted to dispense with the medical examination. In this way the number of physicians available for military service has been increased.

Thanks to the recognized excellent organization of our military sanitary service, the hope may be entertained that the fearful horror of war, so far as regards the wounding of soldiers, will be mitigated so far as possible. Further, from the same reason, we may hope that the epidemic diseases which in former wars have swept away as many or more persons than have fallen on the field of battle, will be excluded, not only from the army, but also from the civil population. That there is danger in this respect has become known to us by a report from Russia where, already for many weeks, cholera is said to be demanding not a few victims in various districts. Even an invasion of St. Petersburg by the plague has been feared.

MEDICAL AND SANITARY AFFAIRS IN VERA CRUZ

(From Our Special Correspondent)

VERA CRUZ, MEXICO, Aug. 28, 1914.

The hot season, which is also the rainy season, begins in Vera Cruz in May or June and lasts until the end of September, and as the season advances the tendency is for the death and morbidity rates for all diseases to increase, due to the heat itself, and the rapid increase in the amount of malaria; yet thanks to the effective work of our sanatoriums, this year is an exception, in that the civil death-rate for July is practically no greater than for June, in which month it was lower than the average.

The civil death-rates per thousand of population, per annum, for the months of June and July for the past five years for the city of Vera Cruz are given below; the improvement for July of this year is too great to be accidental or due to anything but improved sanitation.

	June	July
1910.....	36.86	46.86
1911.....	38.29	46.86
1912.....	44.86	49.72
1913.....	36.86	41.15
1914.....	32.00	32.58

A comparative statement of the civil deaths from communicable diseases for June and July of this year is as follows:

	June	July
Typhoid fever	1	0
Malaria	8	2
Small-pox	4	1
Dysentery	12	4
Tuberculosis	19	26
Diarrhea and enteritis, under 2 years.....	19	14
Diarrhea and enteritis, 2 years and over.....	28	23

The increase of deaths from tuberculosis is not unusual during the hot weather; the small-pox epidemic is over and there are now no cases in the city; between May 18 and July 31, 66,432 persons were vaccinated; revaccinations are now being made when indicated but general vaccinations are now with the end of July. The principal gain is due to the fall in the death-rates for malarial and intestinal diseases and this improvement is directly due to our preventive measures. The antimalarial measures which affect the civil population are three: the suppression of mosquito breeding, the use of the Army laboratory in establishing the correct diagnosis, and the following up and treatment of all proved carriers of gametes in the blood. Mosquito-breeding has been largely suppressed by the extensive and intricate system of ditches in the environs of the city, totaling about 25 miles in length; miles of vacant lots and hundreds of acres of swamp at the bases of the gigantic sand-dunes behind the city have been drained by the Health Department, and it is now possible to

sleep comfortably in almost all parts of the city without the use of mosquito-bars, something heretofore unknown at the height of the rainy season.

Malaria has been made a reportable disease by the Health Department and demonstration of the parasite in the blood is insisted on as far as possible. All houses where proved cases of malaria have occurred have been visited by inspectors trained in mosquito extermination, and secondary cases have been so far practically unknown. As a result of a partial malarial survey of the city, it has been found that the disease is principally localized along the railroad and the railroad yards. Further investigations along this line are now under way. The work has advanced far enough to demonstrate that there is very much less malaria here now than is usual at this time of the year; the Mexican physicians are unanimous in stating that the amount of *paludismo* is now very small.

The other group of diseases which have been brought under control are the dysenteries and diarrheas, and the preventive measures which seem to be directly responsible for the improvement are the following: the suppression of flies and the protection of foodstuffs in the markets by screening; the improvement in the milk-supply; and disinfection and isolation of dysenteric cases. The number of milk-venders in the city is approximately 150, and 200 samples of milk have been examined for dirt, adulteration and the percentage of fat. The milk examinations are made at irregular intervals on unannounced dates, each vender's milk being examined at least quarterly. The measure, however, which seems most directly responsible for the diminution in the number of cases and deaths from intestinal diseases is the antilfly campaign. The city water has been frequently examined in the laboratory and found uniformly good. No cases of yellow fever have originated here or been brought to the port.

The health of the troops has remained excellent, the sick-rate being only 2 per cent. from all causes, or rather less than at most garrisoned posts in the United States. Surgical cases during June and July were few, accidents and injuries, 10 cases; appendicitis, 9 cases; Hagner's operation in about 15 suitable cases has given splendid results. Dysenteries, both bacillary and entamebic have practically disappeared; in May there were 16 cases, in June, 12, in July, 2, and so far in August, 1; the only fatality occurred in May.

Malarial diseases have increased moderately; in May there were 3 cases, in June, 19, in July, 24, and in the first twenty days of August also 24. There have been no fatal and very few severe cases among the troops, since they receive early and proper treatment. Deaths among Mexicans, especially of the poorer classes, have not been infrequent during August of previous years; one Mexican physician of good standing states that ordinarily in August and September, every physician in the city may have 4 or 5 pernicious cases each day, with a high percentage of deaths. The fatalities, they state, are distinctly less since the hypodermic use of quinin has become common. They use 15 grains of quinin bichlorid in 1 c.c. of sterile water; each dose being prepared ready for use in sterile glass ampules. The injection is given deeply into the muscles, care being taken to avoid deposits of fat; abscesses do not follow unless the dose be given into the subcutaneous or fatty tissue. Fatal cases among Mexicans this year are few, and have occurred only among the very poor and ignorant.

The malarial season, beginning in May, lasts to the time of the "northers," cold gales out of the north, which begin to blow toward the end of September. We have, therefore, to look forward to at least a month more of malaria; in fact the worst part of the year is yet to come. The number of cases among both Mexicans and Americans has been kept down to a degree heretofore unattained and every effort is being exerted to exterminate the disease. As it is, many of our cases are imported, and come from localities not under our control. There is no doubt but that the malarial sick-rate of Vera Cruz can be lowered more and more each year, but to accomplish it will require time, brains and money.

No doubt Northern travelers have often wondered why the inhabitants of tropical cities live huddled together in compactly built towns, whose narrow streets are utterly devoid of shrubbery and shade trees. To one who has made a malarial survey of such a town, locating each case on a spot map, the reason is evident, for malaria creeps in through the outskirts of the city from all sides, and does not cease its advance until the older, more densely built portion of the city is reached.

Marriages

HYMAN ISAAC GOLDSTEIN, M.D., Camden, N. J., to Miss Evelyn Lipitz of Vineland, N. J., at Atlantic City, N. J., September 8.

JOHN LADA MILLER, M.D., Alliquippa, Pa., to Miss Florence Nellie Molter of Warrendale, Pa., at Sutersville, Pa., August 27.

THOMAS JOSEPH HOULIHAN, M.D., Ida Grove, Iowa, to Miss Gertrude Masterson of Chicago, at Sioux City, Iowa, August 24.

CARL EDWARDS, M.D., Wade, Ohio, to Miss Iva Keller of New Matamoras, Ohio, at Marietta, Ohio, August 20.

ARTHUR MONROE CALVERT, M.D., Lawrence, Ind., to Miss Anna May Gorby of Indianapolis, September 5.

ALBERT HERR MONTGOMERY, M.D., Chicago, to Miss Elizabeth Russell of Tulare, Cal., August 22.

THOMAS J. W. SHOEMAKER, M.D., to Miss Blanche Papanek, both of Fort Worth, Texas, August 15.

FREDERICK J. ROOST, M.D., Sioux City, Iowa, to Miss Helen Kearney of Jackson, Neb., August 29.

HAROLD H. MEREDITH, M.D., to Miss Mary Adel Palmer, both of Montrose, Colo., August 15.

CYRIL E. SHEPPARD, M.D., Larned, Kan., to Miss Helen Smith of Baldwin, Kan., August 17.

GLENN ORVILLE DAYTON, M.D., Butte, Mont., to Miss Sylvia Magin of Chicago, September 1.

Deaths

George Banghart Henry Swayze, M.D. Jefferson Medical College, 1859; one of the founders and first dean of the faculty of the Medico-Chirurgical College of Philadelphia; assistant surgeon of the One Hundred and Seventy-Eighth Pennsylvania Volunteer Infantry during the Civil War; afterward editor of a weekly newspaper in Mahanoy City, Pa.; died at his home in Philadelphia, August 22, from senile debility, aged 81.

John R. Umstad, M.D. Jefferson Medical College, 1876; a Fellow of the American Medical Association and a specialist on diseases of the eye; surgeon on the staff of the Charity Hospital, Norristown, Pa.; and for many years coroner's physician of Montgomery County; died at his home in Norristown, August 26, from typhoid fever, aged 58.

Charles T. Race, M.D. Tulane University, New Orleans, La., 1882; a member of the State Medical Association of Texas; for more than thirty years a resident of El Paso, Texas; and since 1885 an official of the city health department; assistant city health officer of El Paso; died at his home in that city; May 8, aged 62.

James B. Garvey, M.D. College of Physicians and Surgeons, Baltimore, M.D., 1884; a Fellow of the American Medical Association; for four years sheriff of Calaveras County, Cal., and for two terms superintendent of schools; died at his home in Dunmore, Pa., August 23, from acute gastritis, aged 71.

Arthur Wesley Hammer, M.D. Northwestern University Medical School, Chicago, 1911; formerly of Arbuckle, Cal.; was found dead in the bathroom of his apartment in Chicago, August 30; it is believed from water gas asphyxiation, aged 32.

Jasper T. Englerth, M.D. Physio-Medical College of Indiana, Indianapolis, 1879; physician to the German Baptist Old Folks' Home and Orphanage; died at his home in Honey Creek, Ind., August 12, aged 61.

Frederick C. Beals, M.D. University of Buffalo, N. Y., 1875; a Fellow of the American Medical Association and health officer of Salamanca, N. Y.; died at his home in that city, July 25, aged 62.

Leonard H. Spalding, M.D. University of Maryland, Baltimore, 1869; for thirty-three years a practitioner of Peoria, Ill.; died in Rochester, Minn., August 22, from heart disease, aged 69.

Henry Redlich, M.D. Rush Medical College, 1883; a member of the Illinois State Medical Society; died at his home in Chicago, August 30, aged 82.

PROPAGANDA FOR REFORM

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION

WINE OF CARDUI

The Journal is Sued and the Company is Reported to Be Soliciting Testimonials from Doctors

The manufacturers of "Wine of Cardui" have entered suit against the American Medical Association and the editor of THE JOURNAL for \$300,000.00, presumably for the article regarding this product which appeared recently in THE JOURNAL. We say "presumably," as no details are yet to hand regarding the exact nature of the suit.

In this connection, some interesting data have just been received which we give to our readers in detail. In brief, it appears that the Chattanooga Medicine Company, which manufactures Wine of Cardui, has an agent, or agents, in the field whose purpose it is to obtain testimonials from physicians regarding the alleged value of its nostrum. Accordingly a letter, which we reproduce below, the doctors are expert testimony is desired in support of the company's product. Our correspondent says, further that the physician is told that a retainer will be given for his services and that he will be paid \$25 a day and expenses if he will favor the company by going before its attorney and making a deposition and, furthermore, that if his services as an "expert" at the Chicago trial should be needed, the company is prepared to pay \$50 a day for his services.

Our correspondent's letter detailing the attempts of the concern to obtain testimony of this sort, follows. Names, dates and places have been omitted for obvious reasons:

To the Editor: According to the statement of an agent of the Chattanooga Medicine Company who approached doctors of _____ for the purpose hereinafter stated, that published in a "Chicago paper," has brought suit for damages against that publication. The words "Chicago paper" were his own; as you will learn, particular pains were taken to conceal the fact that THE JOURNAL of the American Medical Association was the "paper" in question.

The mission of this man, according to his own account, was to secure material with which to bolster this suit. The method the Chattanooga Medicine Company is pursuing through him for the prostitution of medical men in Tennessee and Alabama to that end may be of interest to you.

Through the kindness and cooperation of Dr. _____, a local druggist, I have been able to collect the information given here. Affidavits as to any part or all of it will be furnished, if desired, by the gentlemen concerned.

Through the kindness of the activity of Mr. _____, the agent in question. While seeking to "get a line" on local physicians, he told the druggist of his plans and way of working. He vouchsafed the information that he was to employ ten doctors in Alabama and ten in Tennessee as experts for his company; also the fact that he paid each a retainer for his immediate services in signing a certain paper.

On investigation, I found that he had seen two of the three medical men he had decided on as prospects, and had been peremptorily dismissed before getting well launched into his argument. Fortunately, Dr. _____, the third "prospect" was warned that he was marked for a visit. After consulting an attorney, it was decided, in order to learn at first hand the agent's methods, and to secure, if possible, a copy of the paper mentioned above, that the doctor, when approached, should guardedly encourage the gentleman to divulge his offer in full. This was done.

Only pertinent details of the conversation of the first interview are given below; these are just as set down at the doctor's dictation immediately afterward.

William H. Person, M.D. Jefferson Medical College, 1877; a member of the Nebraska State Medical Association and for a quarter of a century a leading practitioner of the Elkhorn Valley; died at his home in Stanton, Neb., August 12.

Thomas Warren Moore, M.D. University of Pennsylvania, Philadelphia, 1869; a member of the State Medical Association of Texas; died at his home in Seguin, Texas, August 19, from cerebral hemorrhage, aged 68.

Robert Francis Gibson, M.D. Harvard Medical School, Boston, 1901; a Fellow of the American Medical Association; of West Somerville, Mass.; died at Hill, N. H., August 16, from heart disease, aged 41.

Samuel Alexander Nicholson, M.D. College of Physicians and Surgeons, Boston, 1904; a lecturer in his Alma Mater; died at his home in Bradford, Haverhill, Mass., August 18, from heart disease, aged 40.

Oliver J. Rowland, M.D. Long Island College Hospital, Brooklyn, 1899; a member of the State Medical Association of Texas and a resident of Sealy, Tex.; died in Boston, Mass., July 17, aged 38.

Ruth Bryant Leake, M.D. University of Michigan, Ann Arbor, 1891; for many years a member of the staff of Battle Creek Sanitarium; died at her home in Asheville, N. C., August 12, aged 58.

Thomas Joseph Murphy, M. D. College of Physicians and Surgeons, Baltimore, Md., 1899; a member of the Maine Medical Association; died at his home in Bangor, Maine, August 14, aged 41.

Uriel S. Wright, M.D. Washington University Medical School, St. Louis, 1871; a member of the Missouri State Medical Association; died at his home in Fayette, Mo., August 15, aged 67.

Patrick H. Mangan, M.D. Kentucky School of Medicine, Louisville, 1903; for ten years a practitioner of Central Falls, R. I.; died at his home in South Attleboro, Mass., August 12, aged 41.

Gustave F. Walker, M.D. Eclectic Medical Institute, Cincinnati, 1872; for nearly forty years a practitioner of New Orleans, died at his home in that city, August 15, aged 73.

John H. Murphy, M.D. Eclectic Medical Institute, Cincinnati, 1875; for seventeen years a resident of Fort Worth, Texas; died at his home in that city, August 18, aged 78.

Clarence K. Alger, M.D. Temple University, Philadelphia, 1909; a Fellow of the American Medical Association; died at his home in Swarthmore, Pa., August 16, aged 45.

John A. Parkinson, M.D. Jefferson Medical College, 1868; surgeon of volunteers during the Civil War; died at his home in North Athens, Tenn., August 17, aged 72.

Ira Zeno Plunkett, M.D. Marion-Sims College of Medicine, St. Louis, 1896; died at his home in Lewis, Iowa, August 13, from cirrhosis of the liver, aged 38.

Grant Safely, M.D. Colorado School of Medicine, Boulder, 1900; of Yreka Cal.; was killed in an automobile accident, near Galt, Cal., August 11, aged 42.

Joseph A. Utter, M.D. Pulse Medical College, Cincinnati, 1885; died at his home in Crawfordsville, Ind., August 19, from angina pectoris, aged 67.

Lee E. Monroe, M.D. Washington University, St. Louis, 1881; died at his home in Eureka, Mo., August 16, from cerebral hemorrhage, aged 55.

Thomas J. Watlington, M.D. Jefferson Medical College, 1857; died at his home in New Boston, Tex., May 26, from senile debility, aged 84.

Nathaniel P. Ward, M.D. Rush Medical College, 1894; died at his home in Saybrook, Ill., August 20, from pernicious anemia, aged 50.

Matthew James Glass, M.D. Trinity Medical College, Toronto, Ont., 1887; died recently at his home in Poplar Hill, Ont., aged 65.

George Nelson Dolbeck, M.D. Hahnemann Medical College, Philadelphia, 1895; died at his home in New York City, July 29.

Marshall Camp, M.D. University of Iowa, Iowa City, 1881; died at his home in Decatur, Iowa, August 14, aged 60.

William H. McConnell, M.D. Jefferson Medical College, 1857; died at his home in Brimfield, Ohio, July 24, aged 83.

Jennie E. Smith, M.D. Chicago Homeopathic College, 1879; died at her home in Chicago, August 20, aged 79.

Edward Thomas, M.D. Rush Medical College, 1860; of Scottville, Mich.; died in Manistee, Mich., August 17.

AGENT: "Doctor, _____ is my name. I am representing the Chattanooga Medicine Company. To state my business briefly, I will say that we are instituting a suit against a Chicago paper which recently made a vicious attack on one of our preparations, Wine of Cardui. At that time it was claimed that Wine of Cardui is freely drunk as booze in the South; also that the women of the South are rapidly being made drunkards by its use. Now, Doctor, we do not believe this to be true. We wish to defend the fair name of southern womanhood from this libel, and in doing so, our product as well. To support us in this suit we want your opinion and expert testimony. You are familiar with Wine of Cardui, I presume, Doctor?"

DR. _____: "Yes."

AGENT: "Do you believe what the paper says?"

DR. _____: "What you have repeated? No, I do not!"

AGENT: "Have you prescribed Wine of Cardui?"

DR. _____: "No."

AGENT: "Have you had opportunity to observe its therapeutic action?"

DR. _____: "Daily."

AGENT: "Is it your opinion, Doctor, that the therapeutic action of Cardui on the female generative organs is due to the alcohol it contains?"

DR. _____: "The alcohol in Cardui, in the prescribed dose, or in any dose, would not, so far as I know, have any special action on the uterus or appendages."

Gratified that no explosion had occurred so far, and beginning to feel sure of his ground, the agent warmed to his task. The physician was here treated to some specious but skilful flattery, which, being irrelevant, we do not give. The doctor was finally asked directly what he thought of the attack on Cardui. He responded: "It sounds interesting."

AGENT: "As I stated at the start, Doctor, it is our desire to retain you as an expert. [Producing a paper.] A retainer will, of course, be paid for your services now. I have here a paper which will give you a good idea of the kind of certificate we want to get. To save trouble, many doctors use it as a guide to go by in writing out their own."

The doctor took the paper and kept it. A copy of this document is enclosed. We have the original. [See "Specimen of Certificate Wanted," below.]

AGENT: "We will, if you will so favor us, require you to go before our attorney and make a deposition as to your belief in the things here set down; that will be better. We will pay you \$25 a day and expenses if you will do this. Also, later, it is likely we will need your services as an expert at the Chicago trial. We are prepared to pay you \$50 a day and expenses for this service."

DR. _____: "But I told you at the start that I had never prescribed Cardui; that I have never observed therapeutic effects that could be attributed to it. If that was the case with a doctor who went to Chicago in your behalf, what could he say that would be of benefit to you?"

AGENT: "That will be all right, Doctor; our attorneys will furnish you the testimony."

At this point the doctor excused himself, promising an audience the next day. I was present at that time. The agent was asked on this occasion what paper was being sued—this question had been purposely withheld before. He did not know. However, being pressed, he finally admitted that he thought it was a journal, possibly a medical journal. The two issues of THE JOURNAL in question were thrust before him. He admitted those contained the articles. His confusion was pitiful.

_____, M.D., _____.

SPECIMEN OF CERTIFICATE WANTED

I have practiced medicine for eleven years, and during that time I have frequently prescribed Cardui for women suffering from menstrual disorders with beneficial results.

I have had patients under my care who have been using Cardui, and I have noticed good results from its use. (Description of symptoms may be inserted here.)

I am positive that the therapeutic results obtained by the use of Cardui are not due to the small amount of alcohol contained in each dose.

I have known of the reputation of Wine of Cardui for many years and know it to be good.

In all my experience as a physician I have never known of the use of this medicine as a beverage.

_____, M.D.
Graduate of _____ Medical College, _____, 19____.

Some Resolutions

In view of the statements given by our correspondent, the following resolutions recently adopted by the Medical Society of Limestone County, Alabama, are of interest:

RESOLUTIONS BY THE MEDICAL SOCIETY OF LIMESTONE COUNTY, ALABAMA

Resolved, That we, members of the Medical Society of Limestone County, Alabama, being present at a regular meeting, and constituting a quorum, do hereby express our disapproval and condemnation of the methods being pursued by the Chattanooga Medicine Company in order to secure material from physicians to be used in a suit for damages against THE JOURNAL of the American Medical Association. Be it further,

Resolved, That we regard as reprehensible the efforts made by their representative, when approaching physicians on the subject, to conceal the identity of the publication being sued. Be it,

Resolved furthermore, That we regard the offer of a sum of money as a retainer to physicians besought to act in the alleged capacity of experts for the company, together with certain sums of money for certificates, depositions and testimony in favor of the said company, as nothing more or less than a technical and legal subterfuge in attempting to bribe and corrupt the members of the medical profession; this offer is so regarded because of the action mentioned in Resolution Two of these resolutions, as well as the fact that local members of the profession have been offered money to sign certificates, and to make depositions certifying facts which they had previously stated to the representative of the Chattanooga Medicine Company, making the offer they did not believe, and in some instances had plainly represented to him as being without the bounds of truth. Lastly, be it

Resolved, That the secretary of this society be authorized to attach to these resolutions the seal of the society; that they be spread on the minutes, and that a copy of the said resolutions be sent THE JOURNAL of the American Medical Association, to neighboring medical societies and to the chairman of the state board of censors.

ANGIER'S EMULSION

Report of the Council on Pharmacy and Chemistry

Angier's Emulsion is essentially a petroleum product. When it was first put on the market commercial interests had been fostering the idea that petroleum products had food-value, and the manufacturers of Angier's Emulsion, making use of the idea, advertised it as a "food-medicine" and an "ideal substitute for cod-liver oil." The impression thus created has been kept alive through persistent advertising in spite of scientific proof to the contrary. To-day many who know that petroleum products have no food-value are still likely unconsciously to class Angier's Emulsion among nutrients. Although the manufacturers now advertise this product as "purely mechanical in its action," they yet show a disposition to profit by the old misapprehension, since, so far from expressly disavowing the old claims as erroneous, they mingle with the new ones vague claims of "tonic and reconstructive merits" apparently designed to sustain, in those who do not take time to consider the evidence carefully, the old faith in the claimed nutritive qualities of the preparation.

While the Council judges a preparation by the claims made for it at present, and not by any past misstatements when these have been thoroughly corrected, the past advertising of Angier's Emulsion so instructively illuminates the scientific worthlessness of proprietary therapeutic claims in general, and the whole course of its history is so typical that the referee has thought it well to review the subject briefly. The Council has authorized the publication of the following report.

W. A. PUCKNER, Secretary.

Angier's Petroleum Emulsion was brought out in 1881—that is to say, before the food-value of petroleum products had been experimentally disproved. Its advertising history

well illustrates the weed-like vitality of a financially profitable therapeutic fallacy. The shifting claims made for this preparation are such good examples of the generally unreliable therapeutic pretensions of proprietary medicines—whether of the "patent medicine" or of the "ethical proprietary" type—that it has been deemed advisable to present a brief review of the conflicting claims made for it at various times.

A PETROLEUM PRODUCT

Angier's Emulsion is described by the manufacturers as containing, in addition to "our specially purified Petroleum," "the combined hypophosphites of lime and soda, chemically pure glycerine, and the necessary emulsifying agents." So far as the hypophosphites are concerned, it is probably unnecessary to remark that the latest researches bring to light no evidence that they influence metabolism in the slightest degree. The Angier Chemical Company apparently accepts this view, for in its advertising stress is laid exclusively on the merits of the emulsion as a petroleum product. It is therefore proper to consider it from this point of view.

The history of the internal use of liquid petrolatum was sketched in a recent Council report.¹ As mentioned at that time, a number of petroleum products were put on the market some thirty years ago as substitutes for lard and butter. Contemporary opinions regarding the food value of such products differed widely.

There never was any scientific evidence to support the view that petroleum and its derivatives are assimilable by the animal organism. In fact, so far as we can learn, there was no scientific investigation of the problem until Randolph's experiments in 1884. These were probably the first to demonstrate the non-absorbability of petroleum and its valuelessness as a foodstuff.

In 1899 Robert Hutchison conclusively demonstrated by experiment that petrolatum, paraffin and related products were absolutely unassailable by any of the digestive fluids, and therefore could not possibly have any food value. Various investigators later confirmed these findings.

FIRST ADVERTISED AS A "FOOD-MEDICINE"

Let us now take up the advertising history of this nostrum. In 1885 it was sold under these claims:

"... a 'Food-Medicine' that is far more than a substitute for cod-liver oil";
"... a Food-Medicine that is readily assimilated and helps to digest other foods."

In 1897 it was an:

"Ideal Substitute for Cod Liver Oil."

In 1899 it:

"... conserves heat and energy by furnishing more material for oxidation."

In 1902 it:

"... supplants tissue waste by tissue reconstruction."

The promoters of Angier's Emulsion thus for some time ignored the status definitely assigned to petroleum products by the experiments of Randolph, Hutchison and others. This was only natural. If petrolatum was absolutely inert in the alimentary canal (and this was now proved beyond controversy) then an emulsion prepared from it most certainly was not a "food-medicine," could not "supplant tissue waste," or "conserve heat and energy." All the credit which previous "unterrified and ingenious advertising" (to quote Hutchison) had accumulated for Angier's Emulsion was bound up with the view that petroleum products were foodstuffs.

LATER ADVERTISED AS NON-ABSORBABLE

The non-absorbability of liquid petrolatum, however, suggested to Robinson, Schmidt, Lane and others, a new therapeutic use for it in the treatment of chronic constipation. This method has rapidly gained popularity and it is not surprising, therefore, that the promoters of Angier's Emulsion

changed their claims accordingly, and now began to base their advertising chiefly on the proved properties of petrolatum. In 1910 the emulsion was advertised for the treatment of chronic diarrhea on these grounds:

"... given by the mouth, it passes to the lowermost portions of the intestines without changing its identity; hence it exerts antiseptic, soothing and demulcent properties upon every inch of the intestinal tract, from the duodenum to the rectum."

The old claims, however, were not discarded altogether, for in 1911 the preparation was recommended for children's diseases as:

"... an aid to appetite and digestion and a splendid tonic and bulder."

Before long the attempt was made to weave together the claims based on opposed and mutually incompatible properties. In 1912 we find Angier's Emulsion recommended because it:

"... corrects digestive disturbance and promotes normal action of the bowels. At the same time it has a most invigorating tonic influence upon the general health."

In 1914 medical men are advised through the advertising pages of the *British Medical Journal* of the:

"... tonic and reconstructive merits of Angier's Emulsion."

A pamphlet on "Constipation," which is "Presented to Physicians with Compliments of the Angier Chemical Company" (copyright, 1913; still distributed in 1914) informs physicians that Angier's Emulsion is:

"... purely mechanical in its action."

Notwithstanding this, we are told later on in the same pamphlet that it:

"... facilitates, hastens and assists the processes of digestion and assimilation." "It is a most efficacious remedy in Pulmonary Tuberculosis because it not only maintains normal nutrition, but also exerts a well-defined specific palliative influence upon the cough and other symptoms of the disease."

Evidently the advertisement is written in the hope that in one paragraph a claim based on the proved properties of petroleum products may be substantiated, while in another a totally different and inconsistent claim may be glibly insinuated in vague phrases designed to lull thought and thus perform the remarkable feat of securing credence for two contradictory statements.

UNWARRANTED AND MISLEADING CLAIMS

Further evidence that Angier's Emulsion is at present exploited both to the medical profession and to the public under claims that are unwarranted and misleading, if not as palpably untrue as the claims made in the past, is found on the wrapper of a trade package purchased in 1914 and in the circular accompanying it. Note the following:

"Indicated in Diseases of the Throat and Lungs and of the Digestive Apparatus. Useful in General Debility and Wasting Diseases, Especially when due to Faulty Nutrition. The antiseptic properties of the Emulsion particularly adapt it to the treatment of diseases of septic or bacterial origin."

"Angier's Petroleum Emulsion is indicated in affections of the throat, lungs and intestinal tract—both subacute and chronic. In diseases of the digestive apparatus due to catarrhal, ulcerative or tuberculous conditions, its peculiar soothing, healing and aseptic properties make its use especially beneficial. Wasting diseases, particularly when due to faulty nutrition, are greatly benefited by its use, one of the most noticeable effects being a prompt and decided increase in weight."

It is, of course, unnecessary to point out that, since petrolatum is non-absorbable, Angier's Emulsion contains no ingredient capable of affecting the respiratory mucous membrane except by local application, for which, indeed, this preparation is evidently not intended.

COMPOSITION AND FORMULAS

According to a circular which was contained in a trade package recently purchased

"Each fluidounce of Angier's Petroleum Emulsion with hypophosphites contains: 33¼ per cent. of our specially purified Petroleum; 9 grains of the combined hypophosphites of lime and soda, chemically pure glycerin and the necessary emulsifying agents."

1. Liquid Petrolatum or "Russian Mineral Oil," Propaganda Department, *The Journal A. M. A.*, May 30, 1914, p. 1740.

As regards the nature of the product referred to under the indefinite term "petroleum" the circular states that Angier's Emulsion is:

"... prepared with refined petroleum specially purified for the purpose. By a process peculiarly our own the crude petroleum, obtained from special wells is so purified that all taste and odor and all objectionable and irritating properties are removed, while the full medicinal value of the oil is retained."

The composition assigned to Angier's Emulsion in an advertising pamphlet "The Petroleum Idea," issued in 1907 differs in that it is said to contain "specially purified crude petroleum" and that each fluidounce is said to contain 2.84 grains of benzoate of sodium. While these quotations convey the impression that certain medicinal constituents of the "specially purified" product obtained from "special wells" are "retained," a pamphlet recommending the use of Angier's Emulsion for the treatment of constipation assures us that it produces the "mechanical effects of the purest petroleum" and that it is "purely mechanical in its action."

LABORATORY REPORT

The statements regarding the identity of the "petroleum" are so unsatisfactory and contradictory (in one place "refined petroleum specially purified for the purpose," in another "specially purified crude petroleum"—in one place "medicinal" and in another "purely mechanical in its action") that the help of the Chemical Laboratory of the Association was invoked to establish the character of the petroleum product and to determine the presence or absence of sodium benzoate. At one time declared by the manufacturers to be present but later omitted from the formula. The Association's chemists reported:

"From a specimen of Angier's Emulsion recently purchased there was separated by the customary methods of analysis, a yellow fluorescent, unsaponifiable, semi-solid residue which has all the properties of ordinary yellow petrolatum of a consistence somewhat softer than the product described in the Pharmacopeia. It was much more dense than the colorless, non-fluorescent liquid petrolatum now in vogue as a laxative. The preparation contained benzoate, both in the form of free benzoic acid and also in the form of a water-soluble salt probably sodium benzoate."

The petroleum product contained in the emulsion was thus shown to be intermediate between the ordinary (solid) and the liquid petrolatum. It also appears that a benzoate is still present, though no longer mentioned in the formula.

2. As is the custom in the exploitation of proprietary medicines, the preparation which is the firm's main output—the leader—is made to do duty as an advertising medium for auxiliary preparations. Thus the Angier Emulsion booklet advises the use of Angier's Throat Tablets. These tablets are alleged to be composed essentially of elm bark and petroleum, are claimed to "promote appetite and aid digestion," and it is stated that "their healing action on all mucous surfaces makes them decidedly beneficial, not only to the pulmonary tract but on the digestive areas as well." Angier's Throat Tablets were examined in the Association's Laboratory to determine the amount and kind of petroleum present in the tablets. Extraction of the tablets with ether yielded a petroleum product which resembled in every way the product obtained from the emulsion. Slightly less than 12 per cent. of the tablet was composed of the petroleum oil. The part insoluble in ether appeared to consist essentially of elm bark, with gum and sugar.

The Laboratory and the Clinic.—There are few more significant principles contributing to form the substratum of good and successful work at the bedside than a just estimate of the correct relationship between clinical and experimental work, and lack of the requisite clearness of mental vision in this matter is, I believe, one of the most potent causes of unexplained disappointment and failure. We sometimes observe a man of high intellectual power, honest, painstaking and industrious, who seems to fail unaccountably, and by that I do not mean in respect of wordly advancement and public estimation, but he fails in the actual practice of his profession at the bedside. If I were asked to state in general terms what in my opinion is the most frequent defect that underlies this regrettable phenomenon, I should reply without hesitation, "Inability to distinguish clearly between the teachings of the laboratory and those of the bedside"—R. Hamilton Russell. *British Medical Journal.*

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted on request.

DISINFECTION OF LIBRARY BOOKS

To the Editor:—1. Can books, say of the circulating department of a public library, be properly disinfected? If so,

2. What is the best method?

3. What would you do with public library books used in families in which there is an open case of tuberculosis (pulmonary) (a) disinfect them, (b) destroy them, and deny family further privileges of the library?

4. Have you any suggestions on this important question of disseminating disease by means of schoolbooks and books of circulating departments of public libraries?

J. VANDER LAAN, M.D., Muskegon, Mich.

ANSWER.—1. Yes.

2. The best disinfecting agent is formaldehyd gas, and the books should be thoroughly opened. They should be arranged on perforated wire trays and exposed to the gas for twelve hours at a temperature of 80 C. (176 F.). When only a few books are to be treated, in the absence of a special apparatus, they may be disinfected by placing two or three drops of a 40 per cent. solution of formaldehyd on every second page. The book is then laid in a closed box or barrel in which more formaldehyd solution has been sprinkled and left in a warm place for not less than twenty-four hours.

3. Tuberculosis is not usually regarded as sufficiently contagious to necessitate the disinfection of books. Without doubt, however, a sufficient degree of safety can be attained by disinfection without denying the tuberculous patient and family the privileges of the library.

4. See THE JOURNAL, April 20, 1912, p. 1201.

The danger of infection of any sort being conveyed by books is very slight. If the books are kept out of circulation for a short time or simply filled with formaldehyd, if they must be "disinfected," no one need fear that books will be much of a factor in disseminating disease.

ANTISEPTIC ACTION OF HEXAMETHYLENAMIN

To the Editor:—Please let me know whether an article was published in THE JOURNAL a few years ago, stating that as a result of experiments carried on, it was found that hexamethylenamin was an antiseptic independent of its formaldehyd content.

S. W. MARICK, M.D., Pittsburgh.

ANSWER.—Such an article has not been published in THE JOURNAL within the last five years. In an abstract of an article by L. B. Wiggs, entitled "Pharmacologic and Clinical Aspects of Hexamethylenamin" (*Southern Medical Journal*, December, 1910, abstracted in THE JOURNAL, Jan. 14, 1911, p. 152) it is stated that "the drug—as such—has only mild antiseptic properties and is probably, in part at least, absorbed unchanged." A statement was made in Queries and Minor Notes (THE JOURNAL, May 18, 1912, p. 1527) to the effect that hexamethylenamin in itself is somewhat antiseptic, but not markedly so. At that time it was believed that hexamethylenamin broke up in the tissues, liberating formaldehyd, and the answer to the query referred to held that the statement that "its value lies in the fact that it breaks up in the tissues and thus formaldehyd is liberated, is fully justified." In an editorial, July 6, 1912, page 38, it is said that "the theory of its (hexamethylenamin's) action centers in the liberation of formaldehyd from the compound on treatment with acid." It appears that the opinion that hexamethylenamin is antiseptic independently of the liberation of formaldehyd was an assumption not founded on reliable experimental evidence. The recent investigations of Burnam, Hanzlik and others have shown that its action as an antiseptic depends on the decomposition into formaldehyd and ammonia, which occurs only in an acid medium.

ORIGIN OF THE NAME "WALDEYER'S RING"

To the Editor:—Please give the origin of the name "Waldeyer's ring" as applied to the pharyngeal, faucial and laryngeal tonsils.

J. W. D.

ANSWER.—This name was given in honor of the German anatomist, Heinrich Wilhelm Gottfried Waldeyer, born in 1836.

New York January Report

Mr. H. H. Horner, secretary of the Examination Division of the New York Education Department, reports the written examination held at Albany, Buffalo, New York and Syracuse, January, 1914. The number of subjects examined in was 8; total number of questions asked, 80; percentage required to pass, 75. The total number of candidates examined was 117, including one osteopath, of whom 73 passed, including one osteopath, and 44 failed. The following colleges were represented:

Book Notices

FEEBLE-MINDEDNESS: ITS CAUSES AND CONSEQUENCES. By Henry Herbert Goddard, Ph.D., Director of the Research Laboratory of the Training School at Vineland, New Jersey, for Feeble-Minded Girls and Boys. Cloth. Price, \$4 net. Pp. 599, with illustrations. New York: The Macmillan Company, 1914.

In this book is embodied a report of the work done during the last five years in the Vineland Research Laboratory. An attempt was made to ascertain the cause of feeble-mindedness of the children in that institution. Three hundred and twenty-seven cases are reported, the research including a detailed study of the heredity as ascertained by a field investigation. The greatest stress is laid on this factor, although each case was thoroughly analyzed from every point of view. The summarized study has led the author to believe that intelligence is inherited according to the mendelian law. This conclusion is, of course, of great importance. Based on so large a series of cases as this, it must necessarily be given the most serious consideration, although this research is but preliminary to further studies along the same line. It has been done with a thoroughness which warrants a belief that future studies will have an equally valuable outcome. The cases are divided up into groups, according to various chief factors underlying the conditions in each instance. There are numerous plates illustrating the features of the different cases, and several chapters explaining the line of study followed and the reasoning process by which Dr. Goddard arrived at his conclusions. The language is simple and the diagrams extraordinarily clear.

DEFENSIVE FERMENTS OF THE ANIMAL ORGANISM AGAINST SUBSTANCES OUT OF HARMONY WITH THE BODY, THE BLOOD-PLASMA AND THE CELLS. Their Demonstration and Their Diagnostic Significance for Testing the Function of Different Organs. By Emil Abderhalden, Director of the Physiological Institute of the University at Halle. English Translation by J. O. Gavrinsky, L.R.C.P., M.R.C.S., M.D., and W. F. Lancaster, M.A. Third Edition. Cloth. Price, \$2.75 net. Pp. 242, with 11 illustrations. New York: William Wood & Co., 1914.

The date of translation of this edition of Abderhalden's work is Feb. 3, 1914, approximately twelve years since the beginning of the fundamental work of the author. In that period there is hardly a single branch of medicine to which the application of this method has not been made. The basic researches are the chief feature of the present volume. The technic of the test is outlined, and there is a chapter on sources of error which will aid the reader toward a greater surety that his work is worthy and reliable. How important this is may be judged from Abderhalden's statement in the preface to the effect that "every research which has not been carried out with absolutely unobjectionable technic delays our arrival at a clear appreciation of the methods." In view of the growth of the subject the author has not attempted to give a complete bibliography, but merely to list and criticize the more important papers which have been published. The time is not yet ripe for drawing final conclusions, but enough has been done to show that important advances are being made. This little guide is a valuable aid to a continuation of the early steps.

DIE OPERATIVEN ERTOLGE BEI DER BEHANDLUNG DES MORBUS BASEDOWII. Von San.-Rat Dr. Otto Klink, Direktor der Provinzial-Heilund Pflegeanstalt in Lublinitz. Paper. Price, 4 marks. Pp. 112. Berlin: S. Karger, 1914.

In this brochure the author carefully reviews the literature of the subjects from 1880 to 1914 and divides this period into two parts, the first from 1880 to 1894, which he calls the old, and the second from 1894 on, which he calls the new. While the number of the articles reviewed is considerably over one thousand, yet the author says that it cannot be said to be exhausted in all directions. Statistics are tabulated showing the results of 6,825 operations for goiter in which Basedow symptoms were present, and 8,992 operations in which Basedow symptoms were not present, making an interesting and instructive study. In the extensive bibliography

at the end, American contributions are conspicuous by their absence. In reviewing the literature in this way it is interesting to note the gradual development of the dominant present-day ideas concerning the nature of this disease and the influence which the operative treatment has had in determining them.

DIAGNOSTIC METHODS, CHEMICAL, BACTERIOLOGICAL AND MICROSCOPICAL. A Text-Book for Students and Practitioners. By Ralph W. Webster, M.D., Ph.D., Assistant Professor of Pharmacological Therapeutics in Rush Medical College, University of Chicago. Fourth Edition. Cloth. Price, \$4.50 net. Pp. 738, with 208 illustrations. Philadelphia: P. Blakiston's Son & Co., 1914.

Less than a year has passed since the publication of the third edition of this work. However, through suggestions from several sources, the author has been able to add to it several subjects not previously discussed and of importance to physicians who wish to be thoroughly conversant with laboratory methods. Among them are, for example, discussions of Kowarsky's method of determining glucose in the blood; several methods for staining spirochetes in the tissues; Lange's colloidal gold test for congenital syphilis, and the newer applications of Abderhalden's method. To those familiar with the laboratory and its uses, no recommendation of this book is necessary. Physicians who desire a ready reference work for the later as well as the commonly used diagnostic methods will find it invaluable.

DENTAL JURISPRUDENCE. An Epitome of the Law of Dentistry and Dental Surgery. By Elmer D. Brothers, B.S., LL.B., Professor of Medical and Dental Jurisprudence in the University of Illinois. Cloth. Price, \$2. Pp. 220. St. Louis: C. V. Mosby Company, 1914.

This is a general review and an analysis of the principles and rules of law affecting the practice of dentistry. Since dentistry is, in a sense, a branch of medicine, the laws, procedures and decisions that apply to medicine also apply to dentistry. As a matter of fact, almost all the references given in this book are to medical cases. The author has presented the subject in a concise manner, and in terms that are both clear and non-technical. It is a book that should be in the hands of every dentist, or at least of those who are not thoroughly conversant with their responsibilities under the law. And, since the matter is so near-medical, physicians will find it full of good advice and information.

Strong Declaration of Liability Against Hospitals with Charitable Foundations

(*Lindler vs. Columbia Hospital of Richland County (S. C.)*, 81 S. E. R. 512)

The Supreme Court of South Carolina affirms a judgment for damages in favor of the plaintiff, who was burned on a hot-water bottle. The court says that this is the first case in that state on the question: Is a hospital with a charitable foundation liable to patients for injuries caused by the negligence of the employees? It has been stated that the doctrine of immunity from damage suits originally arose in cases in which hospitals were operated by government agencies. If the doctrine had been confined to its original declaration, there would have been no trouble; but, when the exempting circumstance does not exist, the immunity ought not to exist. The result of these holdings is that, when a small charitable foundation is secured, a hospital may be opened; patients secured, who go there under an invitation that promises skilled physicians, competent trained nurses; advantages promised that cannot be secured at home; then, when the patients are secured, they may be neglected, burned with fire or vitriol, put into beds from which other patients afflicted with contagious, loathsome, and it may be disgraceful diseases have been taken, and we are told that there is no remedy except to sue, though the injured party may be a poor, overworked, broken-down, friendless, helpless woman. The court is not reflecting on the defendant hospital; it is

ready to believe that the injury here was simply one of those acts of inadvertence that sometimes befall the most careful of men and women. The thing against which it protests is the absolute immunity, given to all hospitals that can secure a charitable foundation, from the most brutal and inhuman treatment of those unfortunate men and women who may be carried (sometimes without their knowledge or consent) within the hospital walls, under an implied contract. Some of the cases hold that the pay patients, when they enter a hospital with a charitable foundation, are really charity patients, and the weekly sums they are required to pay are not payments at all, but contributions to the charity fund. This is brilliant, but is not convincing. This court thinks the first duty of every man and the first call on every fund is to repair the evil of its own doing, and then the remaining fund or remaining strength may be devoted to charity. The court does not think it wise or safe to allow an institution to exist with unlimited power to do evil, and make that institution powerless to repair the evil, because some good man or woman has contributed a fund and intended thereby to do good. The court knows that a trust fund cannot be diverted to a different purpose from that for which it was created; but the purpose of the trust is to relieve suffering, and not to increase it. When, in the administration of the trust, suffering is increased, the purpose fails. The courts that declare immunity are destroying and not maintaining the trust.

Conviction for Publishing Obnoxious Advertisement Affirmed

(*People vs. Kowalski (Mich.)*, 146 N. W. R. 177)

The Supreme Court of Michigan affirms a conviction of the defendant for an offense defined and made punishable by the provisions of Act 164, Public Acts of 1907, namely, that, being a duly registered practitioner in medicine, she inserted or caused to be inserted and printed in a newspaper an advertisement obnoxious to the statute. The jury were instructed that it was not necessary to find, in order to convict this defendant, that she personally went over and caused the advertisement to be inserted. It was sufficient if she caused it to be inserted either in person or by her duly authorized agent. If she was the responsible moving party, who incited or procured the publication of that advertisement, and if it was of the character penalized by the statute, namely, if it was an advertisement with reference to diseases of the genito-urinary organs, or venereal diseases, or containing obscene or offensive matter, she would be just as guilty as though she went over and put it in herself. The mere fact that she did it through somebody else, if she did it, did not relieve her from responsibility; but the jury must be satisfied, in order to convict her, that she knew it was going in, was responsible for its going in, paid for it, knowing what she was paying for. That was a correct statement of the law, which, in the language employed by the court or in some suitable language, the people were entitled to have given to the jury.

1. **Syphilis of Liver Imitating Cirrhosis.**—Cheney urges that in any case that appears to be cirrhosis of the liver, judging from clinical history and physical signs, the blood should always be examined for syphilis. If the Wassermann reaction is positive, vigorous specific treatment will often produce marvelous improvement not to be expected in any other way; but even when the reaction is not positive, the liver disease may be luetic, and so specific therapy may prove of no avail; yet at the same time the therapeutic test will have given valuable information and have done no harm. There is no certain way to tell which case of hepatic cirrhosis is luetic and which is not, except by the blood test, for previous history of infection, or of other earlier manifestations of syphilis, as well as stigmata produced elsewhere in the body by the disease, may all be lacking absolutely; while there may be nothing about the condition of the liver on physical examination or the symptoms it produces, to determine the etiology or to distinguish ordinary portal cirrhosis from luetic.

2. **Syphilis of Vertebral Column.**—Syphilitic spondylitis and perispondylitis while rare, Hunt says, are nevertheless sufficiently frequent to be given careful consideration in every case of acute or chronic rheumatic affection, or may be sudden, simulating an acute rheumatic affection, or it may develop gradually and run an exceedingly chronic and protracted course. Localization in the cervical region, especially, should awaken the suspicion of lues, as more than half of the recorded cases are of this region. It may, however, occur in any portion of the spinal column. Of 100 cases available for analysis, Hunt found that 25 per cent. were associated with some complication referable to the nervous system. These were either of the nerve roots and plexus or of the spinal cord itself. Generally speaking, in this group of cases with neural complications, the symptoms indicated a lesion of the spinal cord in two-thirds; in the remaining third, the neural symptoms were limited to an involvement of the nerve roots or plexus.

5. **Hypertrophy of Thyroid in Dogs.**—According to Hunnicutt three-fourths of the dog's thyroid gland may be removed without appreciably affecting the remainder of the gland. In only 3 of the 59 dogs on which the operation of piecemeal removal was performed did the remaining gland change from a normal to a hyperplastic state. In 5 of the 59 dogs the remaining gland reverted from the early hyperplastic state to the normal state. Where a diagnosis of some degree of hyperplasia was made at the first operation, the pieces removed from the same dogs at subsequent operations had not undergone further hyperplasia. Of the pieces removed from 56 dogs at the first operation, 58 per cent. were normal, 32 per cent. showed early glandular hyperplasia; 5 per cent. marked glandular hyperplasia, and 5 per cent. very early glandular hyperplasia. Definite increase in the size of the remaining gland (hypertrophy) was not observed. The

remains of the thyroid lobes, the accessory thyroids, and the successful grafts in a given dog, presented the same histologic picture. In no dog was myxedema or tetany observed in which as much as one-fourth of the thyroid and one parathyroid gland were preserved.

31. **Diagnosis of Heart Affections.**—The importance of Sahli's announcement of the discovery of his band in 1885 is emphasized by Satterthwaite. The band consists of a wreath of dilated reddish colored venous radicles, usually from 1 to 2 inches wide, disposed in somewhat vertical and parallel lines, though dendritic in appearance. It forms a semicircle on the left side of the thorax over the lower ribs, its center corresponding to the nipple, below which it runs at a distance of several inches. It may escape notice unless one examines the skin closely, for sometimes it is narrow, the radicles are minute, or it is imperfectly developed. It is said to have been noticed in thoracic aneurism and mediastinal tumors, but its significance has not yet been established. Judging from analogy, however, Satterthwaite believes that some intrathoracic deposit of a fibroid material has taken place, as in adhesive pericarditis, calling for a collateral circulation. It is of the same nature as the caput medusae seen over the anterior abdominal wall in cirrhosis of the liver.

35. **Fluid in Pleura.**—This sign is produced by placing the pleximeter finger as near as possible at the base of the spinous process of the vertebra on a level with the suspected fluid and on the side opposite to it, and percussing diagonally through the body of the vertebra in the axis of the opposite lung. If fluid is present the resulting note will be flat. If no fluid is present and the lung is consolidated or normal, the resulting note will be dull or resonant but not flat. If the process is reversed, and diagonal percussion made through

the body of the same vertebra toward a normal or consolidated lung opposite the fluid, the resulting note will be resonant or dull but not flat. This method differs fundamentally from the usual method of spinal percussion, viz., percussing directly over the spinous process in the axis of the center of the vertebral body. This gives a mixed note depending on the condition of the organs on both sides of the spinal column. The method of diagonal percussion described by Mace gives in the same vertebra notes characteristic of the lung toward which the percussion is directed.

40. **Pathology of the Spleen.**—Following splenectomy, King found that there occurs an increase in the total fats and cholesterol in the blood, and also a reduction in the value of the iodine number (that is, a lower iodine number). In clinical conditions associated with hemolysis, pernicious anemia, hemolytic jaundice, catarrhal jaundice and some forms of cirrhosis of the liver, there is found a decided increase in the value of the iodine number. There appears to be a parallelism between highly unsaturated fatty acids in the blood and hemolysis. The occurrence of these highly unsaturated fatty acids is intimately dependent on the activity of the spleen, for removal of that organ reduces the iodine-combining value of the unsaturated fatty acids and renders the production of icterus by hemolyzing agents more difficult. Also it greatly improves clinical conditions in which hemolysis is at work. This is interpreted to mean that the spleen may be the central point in many diseases in which hemolysis and anemia are active, especially in pernicious anemia. This organ may be conceived to take on an increased function as regards its hemolytic activities, resulting in hemolysis, anemia and icterus.

The condition of asplenism presents in some of its features a diametrically opposite picture. Animals in this condition are more resistant to hemolyzing agents, and icterus is much more difficult to produce. The increase in the total fats and lipoids following splenectomy may explain the increased resistance of the red blood-cells found to accompany the condition of asplenism. These substances have definite anti-hemolytic properties. In pernicious anemia, hemolytic jaundice, some types of catarrhal jaundice and cirrhosis of the liver, the hyperactive spleen unfavorably influences the anemia, through its regulation of the highly hemolytic unsaturated fatty acids in the blood. Its removal appears therefore to be indicated. Splenectomy of itself, besides influencing the hemolytic unsaturated fatty acids, raises the percentage of anti-hemolytic substances in the blood; that is, the total fats and cholesterol. King concludes that the fact that total removal of the spleen is not followed by any symptoms dangerous to the life of the patient has probably drawn attention away from the consideration that states of diminished function of this organ may exist.

41. **Influence of High-Calory Diet in Typhoid.**—The Benedict "universal respiration apparatus" employed by Coleman and DuBois in their investigation was tested on normal controls and found to give accurate results. They believe that the apparatus is well adapted to clinical use if Benedict's technic is carefully followed, that is to say, if precautions are taken to prevent leaks, and if results obtained on patients whose breathing is irregular or labored are discarded. Leaks lower the quotient, irregular and labored breathing artificially raise it. The metabolism of liberally fed typhoid patients exceeds that of normal individuals by from 36 to 40 per cent. Previous observers have found that the average basal meta-

bolism during the febrile period of patients who are on diets containing less energy than they produce is 35.3 calories per kilogram per day. Comparing this figure with the averages obtained, after ingestion of food, on typhoid patients who received from 35 to 170 calories per kilogram daily, it is observed that the average metabolism per kilogram of body-weight shows an increase of from 2 to 5 per cent. If the body-surface be made the basis of comparison, it is found that the increase is between 11 and 13 per cent.

Since the variation in the metabolism of different normal persons may amount to 10 per cent. above or 10 per cent. below the normal average, it is obvious that the influence of a large ingestion of food cannot be of great importance in increasing heat production in the febrile stage of the disease. In other words, the large amount of food administered exhibits little or no specific dynamic action, thus removing the chief theoretical objection to the use of liberal diet in typhoid fever. In the high-calory cases approximately 10 per cent. must be added to cover the increase in metabolism caused by bodily exertion incident to moving about the bed. Accordingly the typhoid patients examined had an average theoretical requirement of 38.5 calories per kilogram per day. It has been found, however, that the theoretical requirement must be exceeded by from 50 to 110 per cent. in order to bring the patient into nitrogen and weight equilibrium. The fate of the excess has not yet been discovered. In the steep-curve period and during relapses some patients derived from 84 to 89 per cent. of their calories from carbohydrate and, in addition, transformed some carbohydrate into body-fat. The majority of the high-calory patients showed a sharp rise in the level of the respiratory quotients during the last days of the fever, which we have interpreted to mean that the regenerative processes of convalescence begin before the temperature reaches normal.

43. **Acidosis and Dyspnea in Renal and Cardiac Disease.**—The mild grade of acidosis which is often associated with uncomplicated chronic nephritis, Peabody found, is compensated for by the increased excretion of acids by the kidney. It is only in uremia and usually only in very advanced uremia that non-volatile acids accumulate in the blood in an amount sufficient to cause depression of the tension of carbon dioxide in the alveolar air. In the terminal stage of uremia there may be a high grade of acidosis. Peabody claims that the development of acidosis bears little relation to the accumulation of non-protein nitrogen in the blood or to the output of phenolsulphonephthalein. Determinations of both of these may show extreme abnormalities before any marked degree of acidosis develops. The development of acidosis is not the direct or sole cause of dyspnea associated with cardiorenal disease. A high grade of acidosis may exist without causing a change in respiration which is evident on the ordinary clinical examination.

In some cases of cardiac disease accompanied by dyspnea there is evidence of a slight accumulation of non-volatile acids in the blood, in other cases there is no evidence of such an accumulation. The tension of the carbon dioxide in the alveolar air is normal or very slightly increased. The hydrogen-ion concentration of the blood remains normal. In neither group of cases is the degree of acidosis sufficient to account for the dyspnea on the basis of an increase in the stimulus to respiration alone. It seems probable to Peabody that an important factor in the causation of dyspnea in cardiac disease is an increase in the excitability of the respiratory center. Such a change in the excitability may well be caused by a lowering of the oxygen tension, and be dependent on an inadequate blood-flow.

44. **Clinical and Metabolism Studies in Myotonia Congenita.**—In a metabolism experiment of thirteen days' duration on a case of myotonia congenita, Rosenbloom and Cohoe found that the patient lost 20.02 gm. of nitrogen, while the urinary nitrogen partition (urea, ammonia, creatinin, uric acid and undetermined nitrogen) was normal in character. Creatin was absent from the urine except after the administration of 620 gm. of egg-yolk. In a period of ten days 0.9 gm. of sulphur was lost, while the urinary sulphur parti-

tion (total sulphates, ethereal sulphates, inorganic sulphates and neutral sulphur) is normal in character. In a period of ten days the patient had a positive phosphorus balance of 1.5 gm., showing that during a time of nitrogen loss, phosphorus was retained. The amount of earthy phosphates and total phosphates in the urine may be considered normal. In ten days 4.09 gm. of calcium oxid and 0.56 gm. of magnesium oxid were lost by this patient. A retention of phosphorus produced by feeding egg-yolk did not cause a retention of calcium. Evidence is produced to show that the loss of calcium may play a part in the production of the symptoms of myotonia congenita. The fact embolism was normal in character, with an absorption of about 90 or 91 per cent. of the ingested fat.

50. Use of Section of Scapula in Correcting Nasal Deformity.—A strip of bone, 2 inches long and about $\frac{1}{2}$ of an inch wide was removed by Lothrop from the free vertebral border of the scapula with bone cutting forceps and wrapped in wet, sterile gauze. The attachments of the muscles were first cut from the border and from the external and internal surfaces, great care being taken not to denude the bone of its periosteal covering. A subdermal passageway was made in the nose bridge extending to the distal extremity of the nasal bones. At this point the periosteum of the nasal bones was cut and elevated along the crest of the nose bridge up to the frontal bone. The nasal bones were now ground down with a rasp. The graft was inserted through this passageway and under the periosteum until the end reached to the frontal bone. In three weeks the graft was quite solid and in four weeks it was very rigidly held in place on the nasal bones and the dressing was omitted.

52. Therapeutic Artificial Pneumothorax in Treatment of Pulmonary Tuberculosis.—Of the sixty-two patients treated by Lyon two were incipient ones, and treatment was given to relieve frequent hemoptysis. The lungs in both instances have been collapsed since April, 1913, and February, 1913, respectively. There has been no recurrence of the hemoptysis, and for the past several months, the sputum has been negative to tubercle bacilli. There were thirty-one cases in the moderately advanced stage of the disease, two in which the prognosis was questionable, seventeen unfavorable and twelve bad. In three instances the lung was collapsed to relieve hemorrhage and the experiment was successful. The treatment had to be discontinued with two of the patients on account of a recrudescence of the disease in the opposite lung. One developed a severe hemoptysis in the uncollapsed side and the treatment had to be abandoned. Four had to be discontinued on account of a recrudescence in the opposite lung, in one on account of neurosis, in three because Lyon was unable to introduce a sufficient amount of gas to expect any results. In two instances the treatment was abandoned on account of the occurrence of pleural shock, on both attempts to introduce gas the patient became unconscious.

The treatment was discontinued in still another case which developed appendicitis. One died following a spontaneous pneumothorax and the treatment was discontinued in another case on account of adhesions at the base of the opposite lung, causing marked dyspnea.

Of the fifteen remaining patients, five have been discharged and are doing well, three of this number are at present employed about the institution and are working eight hours per day. The treatment is being continued satisfactorily in the remaining ten cases, many of whom are soon to be discharged.

The greatest number of injections made in a given case was 28, the maximum amount given was 1,700 c.c. and the minimum amount was 50 c.c. with the exception of the patients suffering from pleural shock. Here, none was given. In the twenty-nine far advanced cases the prognosis was unfavorable in ten, and bad in nineteen. The treatment was discontinued in eight instances on account of recrudescence in the untreated side, four on account of neurosis, ten on account of dense unyielding pleural adhesions. One died of acute cardiac dilatation and pulmonary edema. Of the six remaining patients, one has been discharged as arrested and is working in the institution eight hours per day, three are progressing satisfactorily, the treatment was discontinued in another instance on account of pregnancy and the one remaining is a spontaneous pneumothorax and the collapsed lung has been maintained by occasional introductions of gas. The greatest number of injections with any one person was 20, the maximum amount introduced was 1,600 c.c., and the minimum amount was 50 c.c.

Of the sixty-two cases treated, fifty-eight were bilateral and four were unilateral. The treatment was discontinued in thirteen cases on account of dense unyielding pleural adhesions, and in twelve on account of recrudescence of the disease in the untreated side.

67. Effect of Lesions on Hepatic Function.—Oxygenation of the perfusing fluid by pure oxygen instead of air renders more complete the reduction of the ammonia content of the fluid as it passes through the liver. Fiske and Karsner found no difference between normal livers and livers poisoned with the various toxic substances mentioned with respect to their ability to lower the ammonia content of the blood perfused through them.

71. Organic Phosphoric Acid Compound of Wheat Bran.—A previously unknown organic phosphoric acid, inosite monophosphate, $C_6H_{13}O_9P$, has been isolated by Anderson in beautiful crystalline form from wheat bran. All of the salts of this acid, with the exception of the lead salt, are very soluble in cold water. The alkaline earth salts are not precipitated with ammonium hydroxid, differing in this respect from other known organic phosphoric acids as well as from ordinary phosphoric acid.

72. Sugar and Lactic Acid in Blood.—The authors' experiments demonstrate that lactic acid is readily produced in the liver as a result of local stagnation of blood flow. This production of lactic acid, they believe, is probably dependent on the asphyxial condition which is induced, and it is very likely from glycogen that it is derived.

78. Some Anaphylactic Reactions.—Guinea-pigs sensitized to beef or dog hemoglobin fail to react, or react but slightly, to hemoglobins of other origins. The hemoglobins tried were dog, beef, cat, rabbit, rat, turtle, pig, horse, calf, goat, sheep, pigeon, chicken and man. The authors conclude that hemoglobins from different sources are chemically different. A low order of sensitization to isogenous proteins is found in guinea-pigs injected with guinea-pig tissue-proteins.

79. Acetone Substances in the Blood.—A revised technic for the determination of acetone bodies in small samples of blood is described by Marriott. He says that the blood of normal human subjects, and of dogs, pigs and cattle contains less than 1.5 mgm. of acetoacetic acid and less than 4 mgm. of butyric acid per 100 grams of blood, the results being expressed in terms of acetone. In acidosis the acetone bodies in the blood are higher than normal. The highest figure obtained was 28 mgm. of acetoacetic acid and 45 mgm. of oxybutyric acid per 10 grams of blood, expressed as acetone.

94. Strength of Pituitary Extracts.—The use of *B*-iminazolyethylamin hydrochlorid in 1 to 20,000,000 solution is suggested by Roth as a new standard for the determination of the activity of infundibular extracts when the isolated uterus of the virgin guinea-pig is used as the test organ.

95. Cardiac Action of Camphor.—Perfusion of the normal frog's heart with camphor failed to produce any constant effect which, Plant says, can be considered with certainty an evidence of stimulation. Application of a saturated solution of camphor to the exterior of a chloralized frog's heart caused marked but rather transient increase in rate of contraction. Ether solution applied in the same way had a similar though less marked effect.

The rate of contractions in isolated strips of normal ventricular muscle from the turtle's heart, was increased by moderate amounts of camphor in a majority of experiments. The amplitude of the contractions was not increased. Camphor was without effect in chloralized strips.

In the normal isolated dog's heart camphor failed to produce any distinct and constant stimulation; such effects as were observed were too slight and occurred too seldom to be attributed with certainty to stimulation by the drug. In chloralized dogs' hearts and in hearts that showed fatty degeneration from poisonous doses of phosphorus, camphor was without any beneficial effect. Taken as a whole the results of different series of experiments lead to the conclusion that camphor does not produce effects which entitled it to be regarded as a direct cardiac stimulant.

96. Testing Cardiac Action of Drugs.—The drugs tested by Plant were applied at the end of experiments in which camphor had been tested and usually after the heart had been isolated for two or four hours. Caffeine produced a moderate but very distinct degree of stimulation, evidenced by an increase in rate, in amplitude of contractions, in output per minute and a slight increase in the pressure of the blood in the arterial tube leading to the artificial resistance. There was apparently a direct relationship between the increased output and the increase in rate, since the output per beat was not materially changed during the period of stimulation by the caffeine; the relaxation of the heart was slightly less during this period.

Strophanthin caused a marked increase in output per minute and in amplitude of the contractions, and a moderate increase in the pressure in the arterial tube. Changes in rate were very slight, consisting in an increase of two to five beats per minute. The intra-auricular pressure as recorded by a water manometer connected with the inferior cava was decreased. The increase in efficiency of the heart under epinephrin produced a marked increase in the heart rate, in amplitude of contractions, in output and in arterial pressure; the pressure in right auricle was decreased. The effect was very striking but lasted only a short time.

119. **Practical Application of Luetin Test.**—Based on the observations made by about fifty investigators, the following statistical estimation of the practical value of the luetin reaction is presented by Noguchi:

Primary Syphilis.—The reaction is present in less than 30 per cent. of cases and the intensity of the reaction is usually very mild.

Secondary Syphilis.—The reaction was reported positive in 47 per cent. of 630 cases. The reaction is usually mild.

Tertiary Syphilis.—The reaction was found in about 80 per cent. of cases. The reaction is very severe in this stage of the disease (usually pustular form).

Congenital Syphilis.—The reaction was reported to occur in about 70 per cent. of cases. Brown, who made the largest series of tests, found it present in 93 per cent. of seventy-five cases studied. The reaction becomes more distinct after energetic treatment.

Syphilis of the Nervous System.—The reaction is less frequently present in acute syphilitic meningitis than in the parenchymatous affections, such as general paralysis and tabes, where it has been reported positive in about 60 per cent. of cases.

Visceral Syphilis.—The reaction is present in nearly 90 per cent. of cases, especially is it marked in the cases of aortic insufficiency.

With reference to the relation of the luetin reaction to the Wassermann reaction, all investigators agree on one point, viz., that the two reactions do not always run parallel in the same cases. Thus the luetin reaction may be absent when the Wassermann is strongly positive, or the reverse. Both reactions, however, are frequently found to occur in the same patient, especially in cases of congenital syphilis and general paralysis. This discrepancy is explained by Noguchi by the fact that the luetin reaction indicates the allergy and the Wassermann the presence of an active syphilitic process.

Moreover, is it not difficult to explain the reason why a patient in whom the Wassermann reaction was, by a recent energetic treatment, reduced to a negative, should respond more readily to the luetin reaction than before the foregoing treatment, and in this particular respect the luetin reaction is able to furnish the physician with a prognostic measure in a restricted sense. From the statistics of the luetin reaction it is seen that the Wassermann reaction is much more constant among the primary and secondary cases, as well as in general paralysis, but the reverse is the case in the chronic cases, especially in those under treatment.

127 **Gastroduodenal Tube.**—Rehfuß points out that with his modified gastroduodenal tube it is possible, following the technic described, not only to ascertain the whole cycle of gastric digestion, but to locate the presence of liquid rests, hypersecretion, stasis, by a method of insufflation and auscultation described above. It is possible to determine the end point in gastric digestion, by failure to aspirate material when the patient is placed in different positions; by the character of the samples obtained; by the character of the sound produced by insufflation and heard by auscultation; by lavage. A method of outlining the stomach on the principle of the stomach whistles, is possible.

129. Abstracted in THE JOURNAL, July 18, p. 270.

135. **Placental Blood for Transfusion.**—A patient with pernicious anemia received three intravenous injections of defibrinated blood, and one injection in the gluteal muscles, with remarkable results. Rubin's patient was a woman, aged 55 years, with a general history and blood-picture of a typical pernicious anemia. Red blood-cells, 1,100,000; poikilocytosis; megaloblasts; megalocytes; normoblasts; leukocytes, 6,500. She had frequent attacks of dyspnea and tachycardia. She received 6 ounces of defibrinated fresh placental blood, mixed with an equal amount of normal sodium chlorid solution, making a total of 12 ounces. This was injected through a vein in the flexure at the elbow, the blood being kept at about body temperature. The red blood-cells increased 400,000 in less than twenty-four hours. The patient showed signs of immediate improvement. There was no dyspnea nor tachycardia. A week later 16 ounces of blood in normal salt solution were again injected intravenously in the other arm, but after 10 ounces had run in, extravasation took place and blocked the vein, so the balance of 6 ounces was injected in the gluteal region. The red cells increased 200,000 within twenty-four hours. A third injection of 16 ounces of blood in normal salt was made a week later, increasing the red cells 500,000 in twenty-four hours. The patient's general condition improved even more than the blood.

137. **Drop Heart.**—Greene maintains that contrary to current belief both drop heart and its chronic dilatations are extremely common and, indeed, should logically be anticipated in view of our present knowledge of the musculature of such hearts.

They have been hitherto overlooked because of the natural tendency to accept as the normal a standard of measurements far in excess of the drop heart normal and a failure to apply the simplest of therapeutic tests.

Another cause of general oversight has been the absence of serious symptoms of incompensation, apart from dilatation, and the decided dominance of subjective manifestations.

In the absence of proper diagnostic tests, the subjective manifestations are in great measure indistinguishable from those of so-called neurasthenia and nervous dyspepsia, both of which in most instances are directly associated with chronic congenital asthenia and its visceroptoses.

The type of individual carrying congenital asthenia is easily recognizable and in itself at once suggest the presence of the asthenic for drop heart. Greene insists that diagnosis must be based on the basic stigmata, the decided changes wrought by rest, the administration of full therapeutic doses of some standard digitalis preparation and results of repeated careful percussion with modern technic and a full record of symptoms.

The use of digitalis as a test measure is not only justified but required not only for the recognition of masked dilations of drop heart, but for the silent enlargements of degenerative types as well.

The congenitally asthenic heart may initiate symptoms of the most varied character or intensify those originating in other visceroptotic organs or finding expression in the nervous system as a whole.

It is therefore a definite and important contributive factor in those morbid states underlying the greater part of our chronic invalidism.

A few full doses of digitalis, rest modified or absolute, the comparison of carefully determined outlines obtained by modern methods are simple and efficacious means of making a primary diagnosis.

Not all drop hearts are symptom producing nor do the stigmata of congenital asthenia in general mean necessarily that their possessors must be chronic invalids.

Greene believes that dilated drop hearts, while often borne by well nourished individuals without active symptoms, may play a large part in the actual initiation of neurasthenic and dyspeptic symptoms in victims of malnutrition or infections.

- 160 Some Considerations after 13,000 Administrations of Nitrous Oxid. W. I. Jones, Columbus.

157. *Prophylaxis of Ophthalmia Neonatorum.*—Stevenson considers it advisable in the present stage of work for the prevention of blindness from babies' sore eyes, that the old idea among the public that it is always or nearly always gonorrheal in its origin, should be corrected. He urges that the laity should be taught the plain facts, that while a certain small percentage of cases of babies' sore eyes are caused by the gonococcus, the large majority of the cases are produced by the various ordinary forms of pus-producing germs that are likely to be found in any mother; and that the presence of babies' sore eyes does not necessarily imply any guilt or wrong on the part of either parent. So long as the disease is thought to be purely gonorrheal in its origin, there will be associated with its treatment and attempts at its prevention a great deal of unnecessary embarrassment to the family and the physician. If such a belief is prevalent the physician will naturally be afraid, in many families, to suggest the use of prophylaxis, fearing that it will be considered a reflection

on the character of the mother or father, parents also would be afraid to suggest, let alone insist on, the use of prophylaxis. As a not necessarily gonorrheal disease, its public discussion will be much easier, it will receive more respectful attention, and will not be considered a part of the present almost hysteric propaganda with regard to sex hygiene and other subjects that are sometimes too freely discussed.

159. *Hydrophobia.*—The patient whose case is cited by Drysdale and Johnston presented some very unusual symptoms. In the first place, there was absolutely no record or knowledge of a bite by a dog or other animal. Second most of the pain of which this patient complained was confined to his right arm and seemingly had its origin in a recent wound on the dorsal aspect of his second finger. Tetanus, however, was promptly eliminated; there was no evidence or suspicion of trismus, permanent rigidity, orthotonus, opisthotonus or emprosthotonus. A complete review of the history of the case, the nature of the spasms and the rapid progress of the malady was sufficient to show that the disturbance was in no manner related to hysteria. The functional symptom syndrome that prevailed, that is, hemianesthesia, etc., was undoubtedly the expression of his psychopathic constitution.

The reflexes were found to be much slower on the left side as compared to those on the right. The left cremasteric, left plantar and left conjunctival responses were extremely sluggish if not abolished. No clonus Babinski phenomena, Rombergism, or spasticity was elicited. His station and gait were correct. The entire left side of his body, including the face and head, was totally anesthetic, and severe pin prods over this area did not draw blood. The surface sensibility of the right side was slightly hyperesthetic. The line of demarcation between the two sensory conditions was as sharp as the point of a needle. The patient had full control of all bodily movements; the grasp of his hands was strong; the strength of his arms vigorous, and the power of both lower limbs were apparently unimpaired. During a part of their examination, he sat on the edge of his cot and appeared quite jovial and unconcerned.

He was asked if he desired a drink of water, and instantly the typical hydrophobia spasm of the muscle of deglutition and respiration appeared. The facial expression was horrible; the muscles of the neck seemed to stretch almost to the point of snapping, and his eyes presented a "hunted look." He became cyanotic; his mouth was widely opened, and the pulse became almost imperceptible. For a few moments, he struggled to catch his breath, but ultimately relaxed. In a very short time he was quite himself. His craving for water was terrible. His mother handed him a piece of cake which he promptly ate, with little, if any, difficulty. Unintentionally, the word "water" again happened to be mentioned, and again he was thrown into a spasm equally as severe as the one from which he had just emerged.

The patient's throat was carefully examined, and the fauces were found to be extremely congested. A wad of cotton attached to an applicator was inserted deep into the pharynx and no reflex resulted. As a final test, to exclude lysophobia, he was urged to try to relax and slowly swallow a little water. This he tried to do, closing his eyes as the glass of water was brought to his parched lips. Every mouthful was explosively expelled the moment it reached the fauces. The spasmodic seizures increased in frequency and severity. He would scream for water, but the very sight of it would precipitate violent spasms. He was able to drink a little milk and tea to within twenty-four hours of his death. He ultimately became delirious. In one attack, he violently drove his fist through the plaster on the wall, but at no time did he attempt to bite or bark. He succumbed from cardiac syncope, after three hours of almost constant convulsions and maniacal frenzy. A necropsy was performed eighteen hours after death. Sections were made from different pieces of the brain tissue, but no Negri bodies were found. A rabbit and guinea-pig were inoculated with this material. The former subdurally, the latter intramuscularly. The rabbit died the next day, evidently from mechanical injury in inoculation. The guinea-pig is still living.

A portion of the medulla was emulsified in glycerin. August 12, 0.3 c.c. of the glycerin emulsion was injected subdurally into a rabbit. No change was noted until exactly four weeks after, when the rabbit refused to eat. It was drowsy and would continually lie on its left side, it appeared thirsty and drank much water. The next day, its hind extremities were helpless, and when stimulated to move, would drag along and fall over on its left side, apparently exhausted. The next day, its forelimbs were also paralyzed. During the day the paralysis became complete. The breathing became rapid. Death occurred during the night. On examination, grossly nothing was found except a diffuse congestion of the pia mater. Microscopically, Negri bodies were found, also typical Von Gehuchten degeneration of the ganglia.

180. New Supravaginal Plastic Hysterectomy.—This is the uterus-splitting operation with removal of a wedge-shaped piece from the center of the body of the uterus. After separating the bladder from the uterus down to the internal os, Shropshire clamps the uterus on either side from the insertion of the Fallopian tube to its center at the internal os with a specially devised hysterectomy clamp, and using it as a guide, transfixes the uterus at the points of the clamps with a long sharp-pointed knife, bringing the blade out of the fundus at the inner side of the clamp, making a smooth-cut surface; then by drawing the clamps together, he brings the two marginal-cut surfaces of the uterus into close apposition and puts in two rows of chromic gut sutures.

 - 4 *Serum Diagnosis of Pregnancy and of Cancer. A. Leitch.

3. Serum Diagnosis of Pregnancy and of Cancer.—The details of 100 cases examined by Leitch to test the method in the serum diagnosis of cancer are as follows: in the first set of experiments three different substrates were employed: (1) A large protuberant, non-ulcerated squamous-cell carcinoma of the scalp, extremely cellular, with fine supporting fibrous-tissue trabeculae, the tumor being easily washed free of blood and being almost dead white; (2) a cellular spheroidal-cell carcinoma of the breast with a minimal amount of stroma; (3) placenta.

The 9 cancer serums all gave positive results with the epitheliomatous tissue—if anything, more markedly in the case of squamous cell than in other carcinomata—whereas the 12 non-cancerous cases were negative with the exception of a case of lipoma. The mammary cancer was not such a good substrate. It did not give as good results with the mammary cancer cases as did the epithelioma. With it 5 cancer serums were tested; 3 gave positive reactions, 2 were absolutely negative; of 5 non-cancer cases, 4 were negative, 1 was positive. With placenta, 8 cancer serums were tested, 7 gave positive reactions, 1 was negative; of the 7 non-pregnant, non-malignant cases 1 was positive. In all cases the serums were used fresh.

In another series the serums were tested simultaneously against four different cancers: (1) a carcinoma of the breast; (2) an epithelioma of the cervix which it was impossible to free from blood; (3) a protuberant epithelioma of the vulva; (4) an epithelioma of the tongue. With the mammary carcinoma substrate only 4 cancer serums out of 12 gave positive results, and all 3 non-malignant cases were positive; with the uterine cancer substrate 9 cancer serums out of 12 gave positive results, and 1 of the 3 non-malignant cases was positive; with the vulvar cancer substrate 4 cancer serums out of 12 were positive, and of the non-malignant cases 1 was positive; with the lingual cancer substrate 2 of the 12 cancer serums gave positive results, and of the non-malignant cases 1 was positive. The mammary cancer substrate only succeeded in picking out 1 of the 6 cases of mammary carcinoma, the uterine cancer substrate picked out 2 of 3 cases of uterine cancer, and the vulvar cancer substrate picked out the case of vulvar cancer.

Of the 100 cases tested by Leitch to prove the worth of the method in the serum diagnosis of cancer, 51 were cancer and 49 were non-malignant. In the 51 cancer cases positive results were obtained in 28, that is, 55 per cent.; and in the 49 non-cancerous controls positive results were obtained in 18, that is, 37 per cent. In Leitch's opinion, therefore, the method is without diagnostic value.

The conclusions to which Leitch has come after a careful investigation of Abderhalden's dialysation method are that the real fallacies of the technic are beyond control, and that the hypothetical fallacies which Abderhalden invokes to account for false reactions have no bases. Positive results are quite well accounted for by the facts that "substrates" alone, and the serums alone, give diffusible substances reacting with ninhydrin; that the dialysers vary enormously in

the quantities of such substances which they allow to pass in a given time; that serums, influenced by the distilled water and by the presence of a tissue acting in virtue of its physical state, are progressively cleaved; and that it is not the substrate which is split by the serum so much as the serum which is split by the substrate. These real fallacies quite destroy the value of the method, and they cast grave doubts on the whole theory.

As to the value of the method in pregnancy, Leitch states that he may have been unconsciously generous to an attractive theory in his reading of the reactions, but he does not attach much weight to that explanation. It may be that pregnant serum more commonly possesses the property of being split up when some suitable physical accessory is added such as placental tissue. But what seems more probable is that there exists in serum, more frequently, though not exclusively, in pregnancy, a general proteolytic and peptolytic power which we can demonstrate by adding a suitable, though not necessarily a specific protein or peptone. The serum of the normal guinea-pig is generally credited with a fairly strong proteolytic power. Leitch tested the action of several guinea-pig serums on egg albumen, coagulated cancer tissue, human blood-clot, and human placenta, and it happened that only with the latter were strong reactions evident. That seems to show that placenta protein is a suitable substrate for the demonstration of a general proteolytic power.

- 14 *Pregnancy Complicated by Severe Morbus Cordis: Two Cases Treated by Hysterotomy Under Spinal Anesthesia. J. B. Banister.
- 15 Gun Deafness and Its Prevention. J. Horne.

14. **Pregnancy Complicated by Severe Morbus Cordis.**—Banister cites two cases treated by hysterotomy under spinal anesthesia. Case 1.—The patient, a primagravida, aged 21, four months pregnant, had two years previously had a severe attack of rheumatic fever, subsequent to which she developed a mitral stenosis. She had been unwell since the sixth week of pregnancy. There had been very severe vomiting, coupled with dyspnea and edema. She had been kept at rest and treated by the usual cardiac tonics, but reaction had been unsatisfactory. When Banister saw her she was cyanosed and dyspneic, her pulse was 124 and irregular, with the galloping rhythm characteristic of marked failure of compensation. Her temperature was 101.6° F. Examination revealed a normal four months pregnant uterus. The heart was markedly dilated, weak irregular sound with no definite murmur to be heard, but a definite thrill over the whole precordium. There were moist sounds over both lungs, and the base on either side was dull as far as the angle of the scapula. There was no sign of free fluid in the abdomen, but the back and the legs as far as the knees were edematous. As the patient was in a desperate state, had not responded to medical treatment, and was further handicapped by the continued vomiting, it was at once decided to empty the

uterus, and as her general condition precluded any inhalation anesthesia it was thought that the spinal method should be adopted. Accordingly, using Barker's heavy solution of stovaine, Banister produced anesthesia in this way and emptied the uterus by vaginal hysterotomy. The operation was easy of accomplishment and was carried out fairly rapidly without the patient showing any sign of shock. The bleeding was trifling. Unfortunately, the edema of the lungs progressed and she died the next day.

Case 2.—The patient, a 5-gravida, had had attacks of failure of compensation with the last three pregnancies, and extremely trying confinements, and came up in the fifth month of the present pregnancy in a condition of marked severity. The face was cyanosed, breathing was only comfortable when she was sitting up, and she had a distressing cough. The pulse was 118, weak and irregular; temperature 97.6° F. The apex beat was in the seventh space $4\frac{1}{2}$ inches from the mid-sternum, and the heart sounds were weak and flapping in character. There was no murmur. During the next three and a half months she was three times admitted in the same condition but improved under treatment. A week before term she was in a very distressed condition. The symptoms of cardiac failure were all very marked. Banister decided on cesarean section under spinal anesthesia for the following reasons: (1) cesarean section was the quickest method of delivery and the one which would throw least strain on her already enfeebled heart; (2) sterilization could be carried out and further risks of child-bearing avoided; and (3) as her cardiac condition seemed to be one of general myocardial degeneration, a general anesthetic was absolutely contra-indicated. She stood the operation extremely well. The patient got up on the fourteenth day, and left the hospital on the twentieth with her baby, both in good health.

Annales de Médecine, Paris

May, I, No. 5, pp. 469-592

- 16 *Familial Transient Paralysis of Legs Encountered in Northwestern France. E. Lenoble.
- 17 *Paroxysmal Form of Absolutely Irregular Heart Action. (La forme paroxystique de l'arythmie complète.) J. Heitz.
- 18 *Case of Mutilating Disease of the Legs. G. Guillaud and J. Dubois.
- 19 The Thresholds of Renal Secretion. (Signification du terme de seuil de sécrétion.) L. Ambard.

16. **Transient Recurring Paralysis of the Legs.**—Lenoble has encountered six cases in two families and in these alone in ten years of practice in Bretagne. There is evidently some organic lesion of the anterior horns of a certain segment of the lumbar spinal cord and nerve roots. He knows of nothing on record that compares with it, except what is called familial spasmodic dorsal tabes. The segment involved seems to undergo a senile degeneration, presumably from overuse. The paralysis of the extensor muscles comes on suddenly, in one leg at a time, with formication and sense of coldness. First one and then the other leg may be attacked, and the paralysis or impotence of the leg may be more or less pronounced but it passes off in a few weeks or months. The mildness of the phenomena and the pains in the legs suggesting sciatica are special features of the syndrome. The first attack came on at 25, 28 and 32 in one family and at 18, 20 and 24 in the other; all the patients were otherwise robust.

17. **Paroxysmal Absolutely Irregular Heart Action.**—Heitz gives a detailed history of ten cases of complete arrhythmia occurring in paroxysms with or without valvular lesions and with or without high blood-pressure. The paroxysms may develop in connection with some overwork or intoxication or some infection that has touched the myocardium, or even without apparent cause. Such patients are generally neuro-pathic, subject to gastro-intestinal derangements, and sometimes presenting the stigmata of hysteria. Excessive thyroid functioning seemed to be an additional factor in some cases. The heart is generally enlarged and there are signs of arteriosclerosis and of habitual overexcitability of the auricular myocardium entailing fibrillation. The paroxysms may come on with intense palpitations, dyspnea, distress, vasomotor disturbances, swallowing of air and more or less pronounced reduction of the capacity of the heart to do its

work. Attacks of this kind generally last from six hours to five days, and recur at intervals of one to three months. In other cases the paroxysms are much briefer and milder but the intervals are shorter. As a rule the attacks lengthen and the intervals grow shorter in time until finally the absolute irregularity becomes continuous. One patient has had attacks of these paroxysms every two months for nine years. They last six to twenty-four hours but the ordinary rhythm outside of the paroxysms is still normal at the age of 65. Digitalis prolongs and may even bring on the attacks; it is contra-indicated therefore unless there is asystole. Drugs and other measures to soothe the nervous system and tranquillize the patient are the main reliance, supplemented possibly by local applications over the heart region, ice-bags, cloths wrung out of hot water or bags of hot sand. In the intervals the heart should be supervised, with special care for hygiene and diet. When the arrhythmia has become permanent, digitalis may be systematically given to advantage. Morphine should be avoided and the patient reassured that the trouble is purely nervous and functional and will pass off without leaving any traces.

18. **Mutilating Affection of the Feet and Legs.**—The patient was a gardener of 54, apparently free from inherited or acquired taint. In 1905 he cut his heel on a piece of glass and ulceration and trophic disturbances followed, finally compelling amputation of the foot. Seventeen months later intense pains developed in the limb and further trophic ulceration. The other leg soon shared also in the mutilating affection. The differential diagnosis by exclusion was an ascending neuritis entailing secondary reactions in the meninges and spinal cord, possibly drifting into syringomyelia. The Argyll Robertson sign is positive but there are no other indications of syphilis.

Archives Générales de Chirurgie, Paris

July, VIII, No. 7, pp. 769-896

20 *Malignant Transformation of Dermoid Cysts in the Ovary. C. V. de Lapouge.

21 *Tuberculosis of the Clavicle. A. Martin.

22 Fascia Patch to Cure Hernia of Muscle. (Traitement des hernies musculaires par la greffe aponévrotique.) P. Maclaure.

20. **Malignant Transformation of Dermoid Cysts in the Ovary.**—De Lapouge reports three cases of cancer in a dermoid cyst of the ovary and summarizes from the literature forty others, adding that several were of dermoid origin in Stroganova's twenty-two cases of cancerous degeneration of ovarian cysts (*Russky Vrach*, 1913). The presence of the cyst was known for many years in a number of cases before the malignant transformation took place, twenty-six years in one case. But when cancer is once installed it seems to run a rapid course, death following in six months at longest. The malignant transformation had progressed so far in the cases on record before operative treatment was applied that no instance of complete recovery is known. Intervention merely prolonged life a few weeks or months except in one of Tédénat's three cases in which the patient survived for seven years. Dermoid cysts, as a rule, do not manifest their presence until between 20 and 35, and then they are generally removed before there is a chance for malignant transformation. Even allowing for this there are over sixty cases on record of cancer in a dermoid cyst of the ovary. Pommier has reported a case with 4 dermoid cysts, one in the right and three in the left ovary, and two in this group developed cancer. When it has once spread beyond the walls of the cyst, irreparable damage is soon done.

21. **Tuberculosis of the Clavicle.**—Martin states that he knows of no instance of a tuberculous process in the clavicle of a child. The majority of those affected are comparatively young and have a history of tuberculous glandular processes or otorrhea. In one case the process occurred in the clavicle in a young man with inherited syphilis. None of the patients had certain pulmonary tuberculosis but some were regarded as "suspects." Four cases are illustrated, showing that either end of the shaft may be involved. If the latter, the findings are similar to those of spina ventosa in other bones.

23 Dilating and Speculating Cannula for Subglottic Laryngo-Tracheal Stenosis. L. Dufourmentel.

24 *Results of Sanatorium Treatment of Pulmonary Tuberculosis in Various Countries. (Tuberculose et sanatoriums populaires.) G. Artaud.

24. **Pulmonary Tuberculosis and Sanatorium Treatment.**—Artaud compares the statistics from nine countries of Europe during the years 1906 and 1910, comparing the figures for the death-rate and the results of sanatorium treatment, especially in Germany, Switzerland and France. His conclusions are that at least 50 and probably 75 per cent. of all in the early stages of tuberculosis can be permanently cured by the system of public sanatoriums and dispensaries. The main point is to discover the tuberculosis in its incipient stages, when it is always curable. The average stay in the sanatorium should not be less than six months; it is from the sanatorium alone that we can expect actual and durable cures. The tuberculous taking fresh-air treatment at home generally get too much medicine; the family think that drugging is the chief factor in all treatment of the sick. The result in this case is that the digestion gets upset, and when the tuberculous lose appetite and cease to be properly nourished, the downward course is rapid. The family, besides, is seldom skilled enough to ward off further contagion.

25 *Congenital Tuberculosis. W. Möller.

26 *Total or Subtotal Hysterectomy? (Evidement systématique du moignon cervical dans l'hystérectomie subtotale.) De Rouville.

27 Dermographism of Pregnancy. H. Treub.

25. **Congenital Tuberculosis.**—Möller declares that we have no right to assume congenital tuberculosis in any case unless the child dies from it in the first or second week after birth and characteristic lesions are found in it, with tubercle bacilli. Analysis of the cases published as congenital tuberculosis shows that only about a half dozen conform to those conditions. He adds another to this group, the child dying two days after birth and showing lesions of pronounced and typical tuberculosis, with numerous tubercle bacilli. The location of the lesions corresponded to a primary infection of the intestinal tract, spreading by the lymphatics to the regional lymph-glands and from here penetrating at some point into the blood. Recent tuberculous lesions were found in the decidua membrane and panhysterectomy was done. Old tuberculous processes were evident in both tubes, and to these Möller traces the infection of the uterus and of the fetus. When the woman was delivered there was no suspicion of tuberculosis and the placenta was not examined.

26. **Technic for Hysterectomy.**—De Rouville declares that he is a "subtotalist," that is, in removing the uterus he amputates it above the cervix, and he here expatiates on the various advantages of this technic. After the amputation he cuts out with the bistoury the inside of the cervix stump, leaving only a shell a few millimeters thick. The stump is then sutured and peritoneum drawn down to cover it. This leaving merely the shell of the cervix thus links the total and subtotal technics, he declares, with the advantages of each and none of the disadvantages. The vagina is not opened, and thus danger of infection is avoided and there is no tendency to hemorrhage from the vaginal culdesacs, while the weight-bearing apparatus is left intact. Removing the inside of the cervix does away with the possibility of new growths in the cervical mucosa, and if such should develop in the shell left, they can be easily inspected and removed.

30 Spa Treatment and Gynecology. (Traitement hydro-minéral des maladies des femmes.) S. Pozzi.

31 Fibroma in Broad Ligament Accompanying Fibroma in Uterus. X. Bender.

28. **Repair of Perineum Torn Completely Across.**—Pozzi here describes with twelve illustrations the various steps of perineorrhaphy for complete laceration, according to the technic which he has been using for over twenty-five years and with constant satisfaction even in extremely serious cases. He loosens up the anterior wall of the rectum until it is free so that he can draw it down far enough to bring outside the part corresponding to the damaged perineum. By this means there is no suture in the rectal wall except where it joins the anus. This avoids the danger of infection from an intrarectal suture with eventual fistula. The transverse incision in the rectovaginal wall is made in such a way that a small edge of vaginal mucosa is left below the incision; this is a great help in restoring the anus. The incision is carried deep enough to expose the anterior aspect of the rectum. He never found it necessary to open the pouch of Douglas; it can easily be pushed aside by keeping close to the wall of the rectum. He has never had a failure with this technic, and has found it of great service also in rectovaginal fistulas of all heights, first cutting the perineum entirely across to produce conditions similar to those of complete rupture. If there is cicatricial shriveling later, rendering the anus too small, a posterior rectotomy answers every purpose. It is by no means a difficult matter to slit the rectovaginal wall in this way, separating the fibers by working in between them until the orifice of the rectum and of the vagina no longer stand parallel to each other, and can be slipped past each other like bureau drawers. Pozzi illustrates casts made from four quite complicated cases treated in this way thirteen or fourteen years ago, the outcome in all confirming the ease and simplicity and importance of this technic and the fine results and continence attained, and claims priority for the principles involved. He unites the muscles directly by a deep isolated suture, using catgut, and utilizing even mere scraps of the muscles, especially those connected with the sphincter. After this is done he passes two or three double silver wires through all the soft parts just above and crossing the suture of the muscles. The traction on the primary incision has transformed it from a transverse to a vertical incision; this is sutured and the anus restored by suturing the skin to the lower margin of the drawn down rectum, edging the anus, if possible, with a narrow border formed of vaginal mucosa. When all this is done the wires are tightened and tied over rolls of gauze outside. As long ago as February, 1894, Pozzi declared that the lacerated wall should never be sutured directly but be restored by loosening and drawing down the rectum.

29. **Suture of Severed Ureter.**—Sejournet summarizes from the literature seventy-four cases of ureterorrhaphy after complete section of the ureter, classifying them according to the technic applied. The results were better the more perfect the coaptation of the stumps. End-to-end suture is less liable to be followed by stenosis than suture by invagination. The suture should be protected with a small flap, possibly of omentum. The experiences related warn that a large flap of tissue usually shrivels so much that the fibrous retraction may lead to stenosis. It is prudent but not indispensable to leave a small drain or wick. Oozing of urine is generally transient and stops spontaneously but seems to leave a tendency to stenosis later.

33 "Undescended Cecum." (L'ectopie haute du cæcum et de l'appendice et son importance clinique et opératoire.) F. Lejars.

32. **After Evacuation of Empyema.**—De Bovis compares the different methods in vogue for draining after evacuation of empyema, his conclusion being that there is no need to dread the entrance of air as such a serious matter as some claim. Drains and siphons and rubber bulbs and all air-tight procedures can be dispensed with as a rule in treating simple benign empyema. By leaving the low wound open, without tubes or tampons, pus and false membranes escape and the absence of any foreign body leaves a free field to

Nature to heal unmolested. This in itself is the best of all protections against ascending infection. The indispensable condition for this, however, is that the opening for evacuation of the empyema has been made ample enough, and that it was made at the exact point where gravity will prove most effectual to drain the pleura. To ensure these conditions it is necessary to resect a rib and to make the opening for the spontaneous draining at the lowest point of the slope, bearing in mind the patient's position in bed after the operation and during convalescence and whether the empyema is partial or total. He does not hesitate to close the incision and make a new one lower down if the first does not answer the purpose perfectly. He emphasizes further that the mobilization of the chest wall by the resection of a rib permits it to fall in under the pressure of the air so that, outside of the periods of inspiration, it shuts down air-tight over the convexity of the diaphragm and restricts if it does not prevent altogether the inflow of air. Air and microbes are also filtered and kept out more or less effectually by the dressings. As an operation for empyema is generally an emergency operation, the simplification of the procedure and of the after-care is a great gain. De Bovis does not believe that such large openings are necessary as Brinkmann advocates, and his experience with aspiration drainage has shown numerous disadvantages from it. He has applied the technic mentioned above in three cases and has been impressed with the prompt and complete recovery in from three to five weeks (except in the one case of tuberculous origin).

34. **Epinephrin Content of Adrenals in Acute Infections.**—Reich and Beresnegowski report extensive experimental work and clinical investigation the results of which seem to indicate that the epinephrin content of the adrenals is very much below the normal proportion in more than half the cases of acute peritonitis. This lack of normal epinephrin content

readily explains the central vasomotor paralysis and weakness of the circulation which accompany acute peritonitis in man. Their research does not indicate that all acute infections affect the adrenal cortex so rapidly and injure it so severely as was evident in over 50 per cent. of the fatal peritonitis cases examined. This disease takes the lead in this respect. The findings in regard to the staining properties of the adrenal cortex are tabulated from 27 cases of acute peritonitis, 11 cases of chronic infections and 12 cases of acute infections not involving the peritoneum.

36. Perirenal Hemorrhage.—Baggerd reports a case of fatal spontaneous hemorrhage into the bed of the kidney. It proceeded from the kidney itself; in a previous case of extensive retrorenal hematoma the blood came from an adrenal. The typical symptoms of sudden intense pain in the kidney region, signs of severe internal hemorrhage and development of a tumor back of the kidney were pronounced in both cases. In these as also in a number of others on record there had been preceding milder attacks; Lenk's patient had nine in the course of three years. In Baggerd's case there had been attacks every six or eight weeks at first, each lasting two or three days; the intervals were free from pain. These attacks may have been due to preceding small hemorrhages in some cases, but in his case they were explained otherwise by a tendency to hydronephrosis kinking the ureter, and each time the attack had been preceded by a drinking bout, as also the last and most severe attack. The kidney was found floating in a pool of blood and the patient, a man of 44, never rallied after the nephrectomy. The mortality of perirenal hemorrhage is still high, 40 per cent., as the operation generally comes so late. The mortality was 100 per cent. in all the cases under conservative treatment alone. Various operative measures have been applied; the special procedure is not so important as prompt intervention to arrest the hemorrhage.

40. Tuberculosis of the Hand and Heliotherapy.—Hüssy tells remarkably favorable experiences with direct sunlight treatment of tuberculous processes in the hand and wrist, beseeching surgeons in particular to heed his words and refrain from operating in this class of cases and apply heliotherapy. He was assistant to Rollier, and gives the details of 32 cases. In 21 fistulas had already developed in the process in hand or wrist; in 29, lymph-glands were involved, and in 12 the lungs, while other local surgical tuberculous processes were evident in 25. The hand process healed completely under the systematic exposure to the mountain sunlight in 23 cases, and another patient was much improved. These patients have completed their course and left, the functional use of the hand is fully restored in nearly all. Eight others are still under treatment although the hand is entirely healed. In 17 of the 24 cured patients who have left Leysin all other tuberculous manifestations have been cured likewise, and in 5 they have materially improved. Three others have succumbed since to the progressive course of their multiple lesions but without return of the hand process. Heliotherapy, he emphasizes, must be applied only by physicians trained in orthopedic and surgical measures, applying the technic of each as needed, not leaving the entire task to the sunlight. Physicians at the head of tuberculosis institutions must in some way acquire the necessary surgical and orthopedic technic if they accept patients with surgical tuberculosis. The orthopedic side of treatment, punctures, proper position of the part affected, etc., are liable to be neglected when the institution is run by an internist. More use should be made in private practice of the curative action of direct sunlight. Surgical tuberculosis should be brought out of the sick-room into the light and air.

43. Ileus.—Tietze says that in 133 cases of ileus in which he has operated exaggerated peristalsis was pronounced in all cases except those in which peritonitis had already developed or the obstruction was not organic. Wahl declares that strangulation ileus and dynamic occlusion of the bowel both act alike on the peristalsis, paralyzing it. Tietze's

experience thus confirms Wahl's theory and shows further that feculent vomit sometimes accompanies septic paralysis of the bowel from peritonitis and must not be regarded as a sign only of mechanical ileus. The importance of distinguishing between paralysis of the bowel and mechanical obstruction he regards as so vital that he does not hesitate to say that in the former case an operation is a blunder—except when a fistula into the bowel is directly planned—while with mechanical obstruction an operation can be at worst merely hastening the almost inevitably required intervention. He classifies his material under various headings; 41 died of the 81 patients with mechanical ileus; 9 of the 35 with ileus from internal incarceration, volvulus or adhesions; none died of the 4 with torsion of the omentum, but 5 died of the 9 with ileus from necrosis of the pancreas—a total mortality of 42.1 per cent.

50. Juvenile Deforming Arthritis.—Drehmann has encountered nine cases of an affection of the head of the femur in children analogous to coxa vara in adolescents, only it is the reverse condition. Perthes found in similar cases that the surface of the head was flat instead of round and almost a groove had been hollowed out across the top. The cartilage is of normal structure and color and the bone itself seems of normal structure. Whether slight trauma or infection is involved is open to discussion, but there is no question that the deformity is the result of weight-bearing strain. The children affected are between 5 and 10; they begin to limp a little but do not complain of pain. The hip-joint can be used freely except that abduction, either passive or active, becomes impossible. There is no adduction as with coxa vara, but there may be a slight inward rotation. The limp suggests the gait with congenital dislocation. There is no trace of contracture as with an inflammatory process. The limping continues and there may be pain when fatigued, relieved by resting. There is no shortening of the limb as a rule, and after a few years the child ceases to limp and, except for more or less inability to abduct the limb, there is nothing left of the trouble.

70. **Acute Weakness of the Heart.**—Grober comments on the diverse causes which may render the circulation inadequate. In nearly every instance death is the result of the heart's giving out. Acute overexertion is one of the most frequent causes of this and even a normal circulatory system may suffer severely from acute overexertion. The first thing in treatment is to relieve the heart of all the work possible; this is best accomplished by strict bed-rest. He thinks that the bed-rest is the most efficient factor in the "Karell cure." When the left ventricle is not working properly, the peripheral and pulmonary vessels become gorged with blood and great relief may be obtained from venesection. In one case he successfully repeated the venesection (500 c.c.) after an interval of three days. This is particularly useful with sudden and threatening cardiac asthma. Inhalation of oxygen may give great subjective relief, especially in chronic heart disease, but he does not ascribe any objective efficacy to it. The defective heart action may lead to transudation in the pleura, etc., and this hampers the heart action still further and immediate puncture may be indispensable. After tapping of ascites, a pleural effusion may be spontaneously absorbed. Or it may be advisable to drain away all the surplus fluid by several minute incisions 1 or 2 cm. deep in the dorsum of the foot. He has done this in several cases; the wound closed up spontaneously in a week or so.

Other means to influence transudation are to restrict intake of fluids and to stimulate diuresis. Calomel is very useful here but is contra-indicated on suspicion of nephritis. He gives 0.2 or 0.3 gm. calomel three times a day, continuing for three or four days, by which time the urine usually increases to 6 liters or more. The diarrhetic stools under the calomel also aid in throwing off excess fluids, but they must not be allowed to weaken the patient. The patient with acute weakness of the heart is frightened and restless, and this emotional strain aggravates the heart disturbance and calls for a sedative drug, although heart disease reduces the tolerance for narcotics. Grober emphasizes that the physician should keep the giving of the narcotics in his own hand; he does not like to trust this to the patient or his family. When the chronic heart disease is beyond repair and there are periodically recurring attacks of asthma, he does not hesitate to give morphin to abort the attacks.

In acute heart weakness, however, the chief reliance is on camphor, and he urges not to wait until it is a last resort. A subcutaneous injection of camphor seems to ward off the dangerous consequences of morphin on the circulation while not interfering with its action on the nervous system. The camphor may induce nephritis if the kidneys are already below par or if the patient is a child, but the serious condition of menacing heart failure outweighs in importance a possible injury to the kidneys. In acute heart weakness he does not hesitate to make several injections of 1 c.c. camphorated oil (10 per cent.) at five minute or even shorter intervals. When the heart action shows signs of improvement he lengthens the intervals to half an hour or an hour or changes to intravenous injection of some preparation of digitalis. The pressing danger once past, digitalis can be continued by the usual technic by the mouth.

72. **Serodiagnosis of Pregnancy.**—Oeller and Stephan state that the conception of autosensitization under the influence of pregnancy is all that is new in Abderhalden's work, and that his dialysis and optic methods of serodiagnosis have so many sources of error that there can be no question but

that they are based on mistaken premises. They obtained positive dialysis findings in a large number of men while the findings were occasionally negative in pregnant women. They report that by a preliminary dialysis for six hours with salt solution it seems to be possible to get rid of some antiferment bodies which otherwise inhibit or attenuate the digestion of the placenta tissue in the test.

Hirsch calls attention to the change in the concentration of the fluid after digestion of placenta tissue by the Abderhalden technic. If there is no change in the concentration of the fluid then it may be assumed that no digestion has taken place, and this is presumptive evidence of the absence of specific protective ferments. He uses an interferometer to test the fluid before and after for any change in concentration, and reports that tests with this technic have confirmed anew the strictly specific nature of the protective ferments.

74. **Sulphonal Poisoning.**—Pfortner's patient was a previously healthy woman of 30 with three healthy children. She developed manic-depressive insanity after an abortion without known cause. As she was growing rapidly weaker under her extreme restlessness day and night and irregular ingestion of food, she was given 10 gm. of sulphonal in the course of nine days. Obstinate constipation followed and the third day there was retention of urine for twenty-four hours and then the urine presented the typical port-wine tint of hematuria followed a day or so later by vomiting, colic and fatal collapse. Pfortner reviews other cases on record of hematuria after sulphonal, trional or veronal; Günther has compiled forty-seven sulphonal cases, with a mortality of 30 or over 53 per cent.; the outcome in 18 cases is not known but only 8 of the patients are known to have recovered. The disturbances ran an acute course in some and in others dragged over weeks and years. He advocates sodium bicarbonate in treatment. Necropsy has always revealed inflammation and atrophy of the kidneys, but nothing of the kind was found in Pfortner's fulminating case; probably there had not been time for them to develop.

75. **Periodical Arrhythmia.**—Rinderspacher reports the case of a girl of 10, always healthy until diphtheria the year before. Since then she had complained of pains in the back and chest and palpitation of the heart on slight cause. The tracings indicate mitral insufficiency but this does not explain the occasionally recurring irregularity of the pulse. This is evidently due to some periodical tendency to heart-block brought on by functional disturbance of the conducting fibers between the sinus and the auricle, on which becomes superposed at times the influence of stagnation in the coronary veins. This assumption is sustained by the fact that by putting an end to the coronary congestion, the heart-beat becomes regular once more. This case teaches that digitalis may prove useful even for heart-block.

76. **Pancreatitis Following Mumps.**—Dracinski and Mehlmann report that during a recent epidemic of mumps embracing hundreds of cases (Bukowina), three cases developed symptoms suggesting acute pancreatitis, but the syndrome subsided harmlessly in each in less than a week. Recovery was complete in about ten days after the first symptoms of mumps had been noticed. Each patient developed at about the fourth day of the mumps, herpes, intense frontal headache, vomiting suggesting ileus, fever with delirium, collapse, pains and tenderness above the umbilicus, intense acetoneuria and Cheyne-Stokes breathing, and in two the pulse grew very slow. In each of the three the knee-jerk was abolished, as was also the case in 10 per cent. of all the mumps patients examined, and in all the cases with this finding the course of the mumps was exceptionally severe.

77. **Retention of Urine under Morphin.**—Czapek and Wassermann report five typical cases in which complete retention of urine followed a therapeutic dose of morphin. Pal and Hirsch found that spasmodic contraction of the pylorus was frequently observed in dogs after a dose of morphin, and the same mechanism is probably involved in the occasional retention of urine after morphin has been given, the bladder sphincter closing up, and the auxiliary abdominal muscles

being too weak to force it. It has been observed only in men, and it is possible that the retention of urine from this cause may occur after operations on the skull and abdomen and be ascribed to operative shock and other causes.

80. **Sawing the Patella.**—Babitzki's patient has complete functional use of the injured leg and can climb stairs, etc.; a year has elapsed since the operation done to correct dislocation of the internal meniscus of eighteen years' standing. To obtain ample access to the meniscus without injuring the muscles and ligaments, he cut down lengthwise on the median line, sawing through the patella and turning back the halves. The technic has proved so satisfactory that he commends it to others and gives an illustration of the joint thus opened up.

86 Simplification of Endovesical Operations. J. Vogel.

83. **Proliferating Urethritis.**—Lohstein here confirms anew his statements of eight years ago in regard to the necessity for more vigorous measures than usual when urethritis assumes a proliferating type. Curetting may be necessary before the inflammation shows signs of yielding. He gives directions how to do the curetting without injury, saying that he has done it 600 times on 100 patients. In seventy-five of the cases the obstinate discharge became much reduced or disappeared entirely after the curetting done under endoscopic control. He gives an illustrated description of a little roller attachment for the urethroscope which he uses to squeeze out and massage foci of retention in the urethra when there is no actual proliferation of tissue. It may be usefully combined with the curet. The points in which the secretions are most liable to be retained are the prostatic fossula, the bulb and the middle of the pars cavernosa.

84. **Kidney Operations with Bilateral Kidney Disease.**—Casper relates that eight soon died in nine cases of bilateral kidney disease in which the results of functional tests misled him to assume that the second kidney would be equal to the task imposed on it by nephrectomy. He now refrains systematically from operating if—even once—no sugar is eliminated in the segregated urine after the phlorizin test, or if the test with a stain shows tardy change in the tint of the urine, and the tint is merely green, or if the kidney merely stiffens up from lack of the normal reaction to intake of fluids. These are his main criteria for judging the degree of insufficiency of the other kidney. He thinks that tests with alien substances give more reliable findings than those with substances found in the body.

When no sugar is eliminated after the phlorizin test in a case of contracted kidney, this shows that the individual is so impaired that he is scarcely able to stand the removal of the other kidney. If the test indigo-carmin is also eliminated unduly slowly, and there is not the normal polyuria after drinking a given amount of water, it is better to abandon a contemplated operation on the kidney primarily involved. He has made thousands of tests with phlorizin and found that healthy kidneys, without exception, eliminate sugar thereafter. Some mechanical obstruction or defective phlorizin must be incriminated when a negative response is obtained from a healthy kidney. The phlorizin settles to the bottom of the receptacle as the solution cools. Another possible source of error is extreme dilution of the urine from drinking much water. The test is less distinct when the patient is fasting; it is best to allow merely one to three hours after a meal. Considerable albuminuria is also liable to mask the findings of the test. In the few cases in which the negative findings failed to harmonize with the apparently normal condition of the kidneys, the further course of the cases gave the explanation as a hitherto latent contracted condition of the kidney became apparent. Atrophy from pressure can also run a latent course for a time. In a number of cases of

enlarged prostate the kidney parenchyma had wasted away to merely a small strip of cortex, and this can occur without appreciable symptoms. Sometimes polyuria may be the only manifestation of this loss of kidney substance under the influence of pressure.

- 89 *Mesothorium in Treatment of Cancer. P. Zweifel.
90 *Intra-Uterine Application of Radium for Cancer. (Zur Wertung der intrauterinen Radiumapplikation bei Carcinoma uteri.) E. Meyer.

89. **Mesothorium in Treatment of Cancer.**—Zweifel's microscopic findings in cancers after mesothorium treatment confirm the destructive action on cancer cells; the normal cells showed comparatively little change under the exposures. His experience warns of the necessity for extreme care in protecting the abdomen outside of the focus; some stray rays in a few cases evidently did some injury as the patients complained of severe pains and tenesmus and one passed some scraps of bowel tissue in the stools. He recalls two of his older cases of uterine cancer in which the cancer was apparently cured by an extensive local streptococcus process but returned three or four years later. He thinks that the action of mesothorium must be explained in much the same way; the reaction to the mesothorium rays is like a burn, and in the course of this physical process the cancer cells become destroyed and are reabsorbed. It is possible, further, that the reabsorbed cells have a therapeutic action like the autolysates. He urges all who apply radiotherapy to publish an additional report on their cases after a year has elapsed.

90. **Intra-Uterine Application of Radium for Cancer.**—In the first of the two cases under the influence of the endocervical radium treatment a cancer of the cervix subsided completely, leaving merely a considerable defect. In the second case the same technic led to fulminating sepsis, speedily fatal. Necropsy failed to reveal any cause for the difference in the results observed.

- 91 *Clinical Importance of the Systolic and Diastolic Blood-Pressure in Infectious Diseases. (Blutdruck bei Infektionskrankheiten.) J. S. Schwarzwann.

91. **The Blood-Pressure in Infectious Diseases.**—Schwarzwann here summarizes his conclusions from study of the systolic and diastolic blood-pressure in eighty cases of various acute infectious diseases. A high diastolic blood-pressure indicates a tendency to paralysis of the larger abdominal vessels with accumulation of the blood in them, and hence this must be accepted as a sign of the severity of the infection. A lower systolic pressure with a lower diastolic pressure is not a sign that the heart is weakening but only that the vascular tonus is growing less. On the other hand, when the diastolic pressure rises while the systolic falls, this is a sign that the heart is weakening. The importance of these findings for the prognosis and for prompt therapeutic measures is obvious.

96 *Degrees of Detachment of the Mesentery Compatible with Retention of the Vitality of the Intestine. (I vari gradi del distacco del mesentere in rapporto alla vitalità e funzionalità dell'intestino.) P. Azara. Commenced in No. 6.

92. **Tuberculous Process in the Breast.**—Durante adds two new cases to the 150 he has found on record. The tuberculosis seemed to be primary in the breast in one of his cases. Six of the patients were males. The ages ranged from 20 to 40 in the majority and an inherited taint was generally evident. Trauma was incriminated in three cases. When there are other tuberculous lesions the diagnosis is easy when the isolated hard nodules are discovered in the breast, especially when the nodules are adherent to the skin and the lymph-nodes in the axilla display a tendency to enlargement. He insists that amputation of the breast or excision of the focus should be done at once with an incipient or primary tuberculous process but when there are already multiple fistulas, or the mammary process is secondary to tuberculous lesions elsewhere, iodine, locally and internally, with general measures, is the main reliance.

In one of his own cases the microscope showed simple adenofibroma of the breast with typical tuberculous lesions in the lymph-glands surrounding the mamma and in the axilla. The patient was a frail woman of 33 who had never menstruated. The glands around the mamma and in the neck had commenced to enlarge seven years before and there was dulness over both apices. The mammary affection was evidently a retrograde process from the axillary glands, but instead of setting up a typical tuberculous lesion, merely an ordinary fibrous growth was produced. The second patient was a healthy girl of 19 who suddenly developed pruritus in the lower part of the mamma and in a few days a lump appeared, tender on pressure; in five days it developed a fistula. The Wassermann was negative, the skin tuberculin reaction slightly positive. Excision of a scrap the thirtieth day after the first symptoms revealed giant cells but no acid-fast bacilli. The lesion was excised into sound tissue. It was, evidently a primary process. The girl had never been pregnant.

94. **Inguinal Hernia in Children.**—Nota gives an illustration showing his method of blocking the inguinal canal with a sheet of paraffin cut to form a deep crescent which is introduced under the cord, the horns extending upward under the pillars on each side. The canal is then sutured together over the paraffin plate in three tiers. Experiments on animals had demonstrated the smooth healing and permanent integrity of plates made of equal parts of wax and of paraffin with a melting point at 50 C. They are boiled together for twenty minutes and then poured on a sheet of glass to form a plate 3 mm. thick. The wax is absorbed in time, its place being taken by connective tissue which thus forms a solid shield with the paraffin. He has found this method extremely simple and reliable as he has applied it in 150 cases, and it proved equally effectual for two youths of 14 and 18. Some of the children were under 2.

96. **Separation of the Omentum Compatible with Retention of Vitality of Intestine.**—Azara concludes from his experiments on fourteen dogs that separation over a stretch of 5 cm. along the margin of the bowel does not compromise it beyond repair, and hence that up to this distance treatment can be conservative. With separation over a stretch of 6 cm., the functioning of the intestine is so seriously compromised that resection is required unless there is a strip at least 1 cm. wide left still attached to the intestine. This is sufficient to maintain its vitality as a rule. But a stretch 18 to 25 cm. long, even at a distance of 3 cm. from the edge of the intestine, entails inevitable gangrene of the bowel. A stretch up to 15 cm. long, with a strip left on the bowel 3 cm. wide, never was followed by gangrene but cicatricial shriveling sometimes interfered with bowel functioning. Conservative treatment is indicated in this case but the patient should be supervised, ready to operate on suspicion of trouble.

99 Chronic Inflammation and Benign Tumors of the Breast. (Flogosi croniche e tumori benigni della mammella.) A. Cimoroni. To be continued.

97. **Biologic Tests for Cancer.**—Mioni has been making a comparative study of various biologic tests and states that the meiostagmin reaction proved positive in 57.1 per cent. of the thirty-five cases; Crile's hemolytic test was positive in 62 per cent. and in the negative cases the cancer was in an advanced stage or a superficial growth so that the diagnosis was clinically beyond question. On the other hand, in most of the cases giving a positive response the cancers were in the viscera and many of them in the earliest stages of development. The fact that hemolysis occurs also in tuberculosis, etc., scarcely invalidates this test as the clinical manifestations otherwise exclude mistakes as a rule. Elsberg's reaction was obtained only in 11.2 per cent. The antitryptic index was characteristically high in 91.4 per cent. and thus proved its value as an aid in the diagnosis of cancer in dubious cases. The deviation of complement tests did not give reliable results in his hands, and passive anaphylaxis tests also proved uncertain. He remarks in conclusion that after excision of the cancer the various biologic tests all veered more or less promptly to a negative reaction. The details of the various groups tested with the different techniques are tabulated for comparison—a total of thirty-five cancer cases and thirty-five controls, all put through the various tests.

104 The Movements of the Stomach as Studied under Roentgenoscopy. P. C. Romkes.
105 *Fatal Action of Hypnotic in Case of Jaundice. A. Hendriks.

100. **Hemipic Reaction of Pupil as Aid in Diagnosis.**—Bastiaanse expatiates on the importance of determining a hemipic reaction of the pupil. With the extremely simple procedure he describes it is possible to distinguish between central hemipia and hemipia resulting from an interruption in the optic tract. The test can be applied even to a sleeping child, and the findings are more objective than determination of changes in the visual field. An illustrated description is given of a typical case. The patient was a stout woman of 47, who complained seven years ago that her eyesight was growing poor. The hemipic reaction indicated interruption of the optic tract and the further course of the case confirmed the assumption of a tumor pressing on the sella turcica, etc.

105. **Death after Ordinary Dose of Medinal in a Case of Jaundice.**—Hendriks' patient was a well built man of 41 with cirrhosis of the liver, ascites and jaundice. Although confined to bed he was in such good condition that omentopexy was being considered. As he worried over the prospect of the operation and had not slept well for a few nights, Hendriks prescribed a sedative, a mixture of 200 mg. anti-pyrin; 700 mg. medinal; 2 gm. potassium bromid, and distilled water to 30 gm. The patient took, as ordered, one tablespoonful in the evening and slept but did not wake. He was found in coma in the morning, and died the following night with symptoms of pulmonary edema. Hendriks says that no other cause for the fatality could be discovered except the action of the hypnotic in a patient with intense jaundice.

THE HEART IN THE PNEUMONIAS*

ROBERT N. WILLSON, M.D.

PHILADELPHIA

According to the vitality and endurance of the heart and the circulatory system (including its vasomotor supply), may be reckoned the outcome of the given instance of pneumonia. Seldom, if ever, will the mechanical obstruction of the lungs prove a serious factor except in its influence on an already crippled cardiac mechanism. The less perfect the aeration of the blood in its passage through the pulmonary tissue, the more positive is the deprivation of the cardiac structure (muscle, ganglion and nerve) of its proper supply of nutriment.

The importance of this influence is emphasized by the reflection that the blood, under conditions of health, demands over 90 per cent. saturation with natural oxygen as the result of its passage through the lungs.¹ The more complete the stoppage of the blood- and lymph-streams in their course through the walls of the air-vesicles, the more real is the mechanical overload thrown on the pulmonic valve, and soon on a toxemic, tired, right ventricular wall. The more intense and virulent the toxemia, the more certain and extensive will be the damage to the entire cardiac mechanism, vascular, nervous and muscular. Yet there is often to be noted at the necropsy table a surprising discrepancy between the severity of the pneumonic process and of the toxemia, and the apparent damage sustained by the heart.

Many observers have commented on the fact that the heart in certain virulent, fatal pneumonias may appear to be affected in surprisingly mild degree. There may be little or no dilatation, no apparent incompetence of the valves, in short, seemingly no abnormality of a heart in a patient who has from the onset of the toxemia appeared to be doomed in spite of every effort to combat the disease. Such instances are practically always examples of intense, fulminant poisoning, in the so-called croupous or fibrinous type of the disease. The course is brief, the attack is largely on the nervous centers, and the heart, though always participating in the storm, seems to maintain a remarkable degree of power and equilibrium to the very end.

Not infrequently the microscope will reveal appreciable damage that escapes the naked eye. Clinically, as well as at the necropsy, however, the heart-muscle appears to be the last vital force to give way. Not so, in the many instances of bronchocatarrhal pneumonia,

in which we practically never observe a sthenic patient or a heart which gives either clinical or post-mortem evidence of strength, stability or endurance.

One learns to associate the bronchocatarrhal type of pneumonia with a weak, dilated right heart, and on this basis very early to discriminate it from the croupous or fibrinous form of the disease. The temperature is irregular and low, the pulse running, rapid and often irregular, the patient asthenic far beyond the degree commensurate with the amount of pulmonary involvement—such is the clinical picture of the form of the disease in which the cardiac musculature and the vasomotor nervous system seem to sustain to such a preponderant degree the brunt of the attack. After such a pneumonia the post-mortem examination reveals almost invariably a flabby, characterless heart-muscle, of which incompetence is the main feature and dilatation the most meaningful expression. Routier² has recently reported a pneumonia in which the influence of the toxin on the fibers of the auriculoventricular conducting path resulted in a transient heart-block which disappeared spontaneously. By no means infrequently, however, the walls of both the left and right ventricles are thinned, and all of the valves, pre-eminently the pulmonic and tricuspid, are insufficient. I have one interesting specimen in my collection (Fig. 2) in which the conus arteriosus and the pulmonary artery both show marked permanent stretching and distention, the pulmonic valve appearing wide open between.

THE MICROSCOPIC CHANGES

I think it permissible to say that the heart shows post-mortem evidences of the toxemia in every fatal case of fibrinous, as well as of bronchocatarrhal pneumonia, that reaches the microscope. In the latter type of the disease the changes are more likely also to be macroscopic. I think it likely that every heart that weathers the pneumonic storm sustains similar lesions, of milder degree perhaps, yet from which it probably never fully recovers.

During the past year I have taken great interest in studying microscopic sections of the cardiac musculature from fatal cases of pneumonia in the wards of the Philadelphia General Hospital. In not a single instance was there a lack of evidence that a toxic influence had been actively at work. Usually the process appeared in the form of an acute diffuse myocarditis, with cloudy swelling of the cells, often with fragmentation of the muscle-fibers. In the great majority of cases the striations had nearly disappeared from the fibers, over wide areas, if not generally throughout the heart. Not infrequently could be found here and there areas showing extensive round-cell infiltration,

2. Routier: *Arch. d. mal. du coeur*, May, 1914.

mainly of the interstitial substance between the fibers. In quite a number of instances, as exemplified in Figure 3, there was wide-spread hemorrhagic infiltration. The nuclei of the muscle-cells were proliferated, were often swollen, and here and there vacuoles appeared in their place. Many of the muscle-fibers gave the appearance of being atrophied. In no case except in old persons, or in those afflicted with organic cardiac

Fig. 1.—The heart-muscle in a case of croupous pneumonia, showing the rich capillary blood-supply to each fiber, the capillaries lying within (or in a groove in) the latter (C); inter-fibrillar hemorrhage (H), and complete loss of striae.

disease, was fatty degeneration of the heart-muscle observed.

Macroscopically as well as microscopically, there was evidence in every heart examined of some degree of pericarditis. I observed not one instance in over a year's time of fresh endocarditis, except such as was superimposed on an old lesion.

THE BLOOD-PRESSURE

Before using the blood-pressure as an evidence of either cardiac competence or insufficiency in the pneumonias, it is incumbent on us to show that in a sthenic pneumonia the customary or normal pressure is due to an overacting or at least a capable heart; while in the low-grade or asthenic pneumonias the low pressures are due to an incompetent cardiac mechanism rather than to vasomotor failure. The personal equation will of necessity enter largely into the verdict rendered by various investigators of this question. During the past three years I have studied more or less thoroughly over seven hundred cases of pneumonia on the wards of the Philadelphia General Hospital. Both with the finger on the radial, carotid and apical pulses, and with the sphygmomanometer, I have measured the blood-pressure in very many of these cases. I have a few records of the systolic pressure made in certain sthenic fibrinous pneumonia cases reading as high as 170 and 180 mm. of mercury. Far more often the readings followed approximately the normal line (from 120 to 140 mm.). I refer, of course, only to the active and sthenic stages of the toxemia. I have yet to see in a patient with pneumonia

of the bronchocatharrhal type (except in childhood) an instance of high or even of normal systolic blood-pressure. Even in instances associated with symptoms of nephritis, or with arteriosclerosis of high grade, there has persisted a low systolic pressure, indicating insufficiency of cardiac vigor and driving power.

The diastolic pressure, elicited by the auscultatory method, furnishes a fair index of the vasomotor tone. While this also is usually lowered in pneumonias of the asthenic type, it falls by no means in a measure commensurate or parallel with the cardiac power. Thus the systolic pressure in cases of bronchocatharrhal pneumonia during the stage of active toxemia has averaged not far above 100 mm., while the diastolic pressure has seldom registered below 80 mm., yielding an average pulse-pressure of 20.

This fact, together with such manifest indications of cardiac insufficiency as systolic jugular pulsation, arrhythmia, small rapid pulse, enlargement of the area of cardiac dullness to the right, and often a series of valvular murmurs that can only be interpreted as indicative of muscular (relative) insufficiencies, apparently allow us but one possible conclusion, namely, that in the great number of low-grade pneumonias the heart-muscle must be ever an object of care and concern. Gibson³ has called attention to a possible prognostic relation of the systolic cardiac pressure to the pulse-rate. Lauder Brunton has made a similar study of the diastolic pressure. In my own experience the systolic pressure has furnished a very uncertain prognostic index, for the reasons already stated. The majority of the low-grade pneumonias have presented a systolic pressure almost constantly lower than the pulse-rate, and yet the vast majority of these patients, when properly treated, have recovered.

THE INFLUENCE OF TREATMENT

Considerable evidence may be gained as to the actual condition of the cardiac mechanism through studying the results of treatment. It is a current belief and

Fig. 2.—Pneumonia heart, showing (A) dilated conus arteriosus and right ventricle from without, and insufficient tricuspid (B) and pulmonic (C) valves.

teaching, employed perhaps more freely than is justified by circumstances, that the pneumonic patient dies not of his pulmonary involvement, and not of his cardiac embarrassment, but owing to paralysis of the vasomotor system. In acute fibrinous sthenic pneumonia there would seem in certain instances to be at

3. Gibson: *Edinburgh Med. Jour.*, 1908, lxx, 22.

least some reason to support this view. In the bronchocatarrhal type of the disease there is exceedingly little. No better illustration could be given of the truth of this assertion than the fact that the high or normal blood-pressure in the fibrinous type appears to be due to overaction of a sthenic heart; while conversely, in the bronchocatarrhal form the asthenia and the almost invariably low blood-pressure appear to be

otherwise healthy, non-alcoholic men and women should recover. Not so with the bronchocatarrhal, asthenic pneumonia patient, who must be supported actively through the disease because his vital forces, especially his cardiac mechanism, are all below par. Many a case of mistreated pneumonia takes on a totally different appearance when placed under conditions that favor and nourish instead of depleting the tone and strength of the heart. Perhaps the best illustration may be had in the misuse of cold air on an asthenic patient suffering from pneumonic toxemia. I have placed many such shivering, cyanotic subjects in warm, clean air and witnessed the immediate reestablishment of forces that were fast beginning to wane. Uppermost and most striking of all appeared to be the influence on the heart, which craved oxygen as its natural stimulant and tonic, but needed it in the form of warm, as opposed to cold, clean air.

PREEXISTING CARDIAC DISEASE

A final bit of evidence as to the importance of a thoroughly healthy cardiac mechanism—including musculature, valves, endocardium, ganglia and nerves—is observed in the high mortality of cases that enter on a pneumonic toxemia with preexisting cardiac disease. We have all seen instance after instance of a patient making a bold fight to weather the storm, and experiencing sudden cardiac collapse, either in mid-stream or on the brink of convalescence. Only recently I witnessed an acute pneumonia in a young man of 22 years, an alcoholic, with myocardial degeneration and high-grade mitral stenosis and insufficiency, all sclerotic and probably syphilitic in origin. He went to bed in the beginning of an intense pneumococcus infec-

Fig. 3.—Heart-muscle from the left ventricle in a case of bronchocatarrhal pneumonia. Extensive degeneration of the fibers, with wide spread hemorrhages (H). Striae completely lost.

due not nearly so much to loss of vasomotor tone as to actual cardiac dilatation and disability. Instances that admit of reestablishment of the cardiac tone do well. The most telling advantage seems to come from the systematic and thorough emptying of the intestinal tract, in many cases the manufactory of the toxic products. When the bowel has been deliberately rendered and kept clean the heart has, in my experience, seemed to have its best opportunity for rehabilitation. The moment the bowel has been neglected the heart has apparently suffered in a measure that is not to be explained on the basis of mere mechanical embarrassment. Such remedies as nux vomica, quinin, camphor, digitalis and oxygen in Nature's own form of warm, clean air, may serve as cardiac tonics and, on occasion, as indispensable temporary crutches. Under their influence the blood-pressure rises and may be maintained at a more favorable level.

On the other hand, such drugs as epinephrin and pituitary extract I consider dangerous in the presence of a weak heart. While they are certain to afford a momentary rise in the blood-pressure as the result of their influence on the vasomotor system, I have more than once seen evidence of their mischievous, and possibly lethal, action on a weak heart, through the imposition on its crippled musculature of an additional load in the form of a tense peripheral circulation. Nature knows better than we when to elevate and when to lower the intravascular tension.

In a sthenic fibrinous pneumonia practically any treatment may be employed. We start and finish with the knowledge that in the vast majority of instances,

Fig. 4.—Heart-muscle in a case of bronchocatarrhal pneumonia. Striae show here and there, but have mostly disappeared. Considerable fragmentation of the fibers (F). The capillary blood-supply is beautifully distinct (C).

tion with a heart widely dilated, an irregular pulse and edematous extremities. Within two days he showed a steady, remarkable cardiac gain. The jugular pulses became almost undiscernible, the apical pulse regained its regularity, the edema entirely disappeared from the extremities. With these signs of cardiac rehabilita-

tion, the whole aspect of the pneumonia (croupous or fibrinous, as shown at the necropsy) altered. The patient was no longer cyanotic, the breathing became more free, and it appeared almost as though even this desperate case might win out against the acute disease. Suddenly and coincidentally with an apparent crisis, all the signs of cardiac distress reappeared, and in a brief period evident cardiac, not pulmonary, death supervened. The heart had reached its recuperative limit, and could draw no further on a reserve force, because it had no further stock in store. In the same manner a tobacco- or alcohol-weakened cardiac muscle may decide the issue between life and death in an otherwise favorable pneumonia.

CONCLUSION

Without attempting to minimize the influence of the vasomotor system in the causation of a high mortality in pneumonia, it would seem as though we ought not to be satisfied, on the basis of either clinical or laboratory experience, to regard the heart in any other

Fig. 5.—Heart-muscle in a case of bronchocatharrhal pneumonia, showing considerable atrophy of the fibers, scattered hemorrhages (*H*) and extensive fragmentation (*F*). Striae are seen here and there (*S*). Capillary blood-sunily is exquisite (*C*).

way than as the factor of prime importance in the safety or danger of the great majority of asthenic pneumonia patients. More and more does the prevalent pneumonia seem to be tending away from the well-recognized, frank sthenic type, to the low-grade, asthenic, bronchocatharrhal forms. The more certainly this is true, the more inevitable will be the necessity of safeguarding the heart from start to finish, not so much by the use of drugs as by their avoidance (especially cardiodepressants like nitroglycerin and alcohol), not so largely by treatment as by the studious prevention of an overdose of solicitous care. Hygiene of the intestinal tract, sane feeding, the intelligent use of an abundance of clean air of the right temperature, and the insuring of ample periodic freedom from the doctor, nurse and family will go farther than any others toward supporting the organ whose staunch cooperation is essential to the happy outcome of the case.

1827 Spruce Street.

ABSTRACT OF DISCUSSION

DR. JAMES M. ANDERS, Philadelphia: I feel convinced that Dr. Willson is right in stating that pneumonia has been assuming an irregular bronchopneumonic type in recent years to a greater degree than formerly. This fact may be attributable to the more constant and general prevalence of various forms of influenza. The view that death in uncomplicated cases of pneumonia is due to the specific effect of the toxemia on the heart is widely accepted. Perhaps it would be more nearly correct, in the present state of our knowledge, to say that death is caused by the general rather than the local effect of the toxemia. As pointed out by Dr. Willson, the whole vasomotor system is profoundly involved in many cases. The heart is frequently dilated, especially the right side, and filled with firm coagula. It has long been held that if the more usual cardiac complications, such as acute endocarditis, pericarditis and fatty degeneration in protracted cases, be excluded, the changes presented by the myocardium are conspicuous by their absence. The results of the microscopic studies by Dr. Willson, therefore, are not a little surprising, but will constitute a distinct advance in our knowledge of pathologic changes found in the heart in pneumococcal infections, especially if confirmed by the findings of other competent observers. The frequency and seriousness of the disease in question make it desirable that further histologic investigations of the subject be undertaken. I quite agree that cold or fresh air in the treatment of pneumonia is one of the best, if not the best measure at our command, but it should not be indiscriminately employed. It has not a specific influence, but does increase resistance to the toxemia. Again, it should not be employed in cases in which active kidney lesions preexist.

DR. WILLIAM S. THAYER, Baltimore: Does Dr. Willson believe that the type of pneumonia has really changed from a sthenic to an irregular asthenic type? On what does he base his opinion? In over twenty-five years' observation of pneumonia in various regions I have not been able to detect any essential differences in the clinical character of the disease beyond, of course, the common variations in different epidemics. I am quite familiar with this assertion with regard not only to pneumonia but to other acute febrile diseases, especially typhoid fever. I rather think that the old-fashioned "typical case" is essentially a picture in the mind of the observer based on text-book descriptions—an impression so strong that in the course of years it becomes interpreted as actual experience; and that the common impression that such a disease as pneumonia is changing its type is largely based on the circumstance that in practice pneumonia shows frequent variations from this picture. I am not aware that such change in the clinical manifestations of the disease has occurred.

DR. ROBERT N. WILLSON, Philadelphia: In answer to Dr. Thayer's question, I have two grounds for the assertion that the prevalent type of pneumonia is gradually changing from that of the old-fashioned book type of fibrinous or croupous pneumonia to the low-grade or bronchocatharrhal form. First, my own personal experience in a series of several hundred cases, both in hospital and private work, leads directly to such a conclusion. This experience covers and includes considerable necropsy and microscopic work in confirmation of the diagnoses. My second basis of argument is the result of not a few conferences held with men in various localities over the country, who agree with me in my conviction as the result of their experience and study. Dr. Anders' statement, made a few moments ago, in discussing my paper, furnishes a case directly in point. I had not previously heard his position in the matter. I shall welcome similar studies of the heart in the pneumonias as confirmatory of my own. In every instance of pneumonia widespread damage to the cardiac musculature will be found. When this fact is recognized I think we will begin again to regard the heart as the organ and force mainly to be safeguarded and conserved, and to lay a little less stress on the vasomotor factors in grave cases of pneumonia.

THE USE OF SMALL DEEP SKIN GRAFTS

JOHN STAIGE DAVIS, M.D.

Instructor in Surgery, Johns Hopkins University
BALTIMORE

The object of this paper is to call attention again to the value of very small grafts, especially to those which contain more of the true skin than the superficial grafts advocated by Reverdin. I have called these grafts "small deep grafts."

The hastening of the healing of granulating wounds by the use of small detached bits of skin was first demonstrated by J.-L. Reverdin.¹ His report to the Société Impériale de Chirurgie, Dec. 8, 1869, caused universal interest.

He showed a patient on whom he had practiced "epidermic grafting," and described the grafts as consisting of the epidermis only. He says, "I raised with the point of a lancet two little flaps of epidermis from the right arm, taking care not to cut the dermis."

Grafts obtained by Reverdin's method are usually

in character than when the thinner grafts are used (Fig. 1).

It is interesting, when we consider that Reverdin developed his method of grafting before the introduction of antiseptics and asepsis in surgery, and that his is probably the only type of graft which could have given satisfactory results under such conditions.

The favorable results obtained by other surgeons in England, America, Germany and France, following the use of Reverdin's method, undoubtedly stimulated further investigation along this line.

The tiny grafts of Reverdin were gradually superseded by much larger grafts of the same thickness, advocated by Ollier³ in 1872, and later by Thiersch⁴ in 1886. After a few years the value of the Reverdin method seemed to have escaped the attention of most surgeons, and one might be about a surgical clinic for years and never see this type of graft employed.⁵

USE OF SKIN GRAFTS

As there is little difference, except in thickness, between the "small deep grafts" and Reverdin grafts,

Fig. 1.—Photomicrographs of the same magnification showing the comparative thickness of a small deep graft and a Reverdin graft; A, a small deep graft cut to include a considerable thickness of the true skin; in the section the edges of the graft are curled inward; B, a Reverdin graft cut to include as little of the dermis as possible; there is a thin layer of the dermis throughout, which is thickest in the center.

thought of as pure epidermic grafts, and in his articles Reverdin always spoke of them as *greffe épidermique*; but in his exhaustive paper on the subject,² published in 1872, he says in part, "The title 'epidermic grafts' is not perfectly correct, as the transplanted bit is composed of the whole epidermis and a very little of the dermis."

Reverdin also said that if the epidermis alone could be transplanted, the same result would be obtained as when a part of the dermis was included. This, of course, is true as far as the epithelium is concerned, but it has been my experience in a large number of cases that the grafts which are somewhat deeper and contain more of the true skin give a more stable healing, and the final result is more like the normal skin

the following methods of preparation, etc., will be found applicable for either type.

Surface on Which Grafts May Be Placed.—The grafts may be placed on fresh wounds, but are usually applied to granulating surfaces. The success of small grafts depends to a large extent on the condition of the granulating wound, and it is most important that the granulations be clean, firm, rose pink in color, and not exuberant. Time is saved in the end by careful attention to this point. It is of advantage to place

5. In a study of the first 550 cases grafted in Dr. Halsted's clinic at the Johns Hopkins Hospital, between 1889 and 1909, I found that Reverdin grafts were used in only two cases, and then in conjunction with Thiersch grafts. Since that time, however, the small grafts have been frequently used (Davis: Johns Hopkins Hosp. Rep., xvi). In 1909, Ehrenfried and Cotton, in an excellent and timely paper, again brought to the attention of American surgeons the value of Reverdin's method. In this paper there is also a complete historical review of the subject (Ehrenfried and Cotton: Boston Med. and Surg. Jour., Dec. 23, 1909, p. 911).

these grafts on a granulating surface, as there is no pain in the preparation of the surface; no danger of stirring up infection, and no loss of blood, which is an important point in cases already much depleted.

I will not consider at this time the various methods of bringing a granulating surface into healthy condition.

Method of Preparing Healthy Granulations to Receive Grafts.—On the day preceding the operation, all secretions and crusts are removed. The granulations are painted with tincture of iodine and dressed

ready to apply the grafts. It is most important that the surface to be grafted should be perfectly dry, as the grafts adhere much better to a dry surface, and are less liable to be subsequently displaced.

The Source of Grafts and Area from Which They Are Obtained.—Autografts are almost uniformly successful when placed on a granulating surface which is in proper condition.

Isografts are also successful in many instances, but there are wounds which have come under my observation on which no isograft would take, even after

Fig. 2.—A, the straight intestinal needle, held in an artery clamp, with its point engaged in the skin. The skin is raised up in a little cone. B, the scalpel cutting through the base of the cone. C, placing the graft on a granulating surface. A large opened-out safety-pin is very useful in detaching the grafts from the needle. In this photograph none of the grafts have as yet been pressed down on the wound, and the edges are still curled under.

either with balsam of Peru and castor oil, 1:3, or with moist boric or salt gauze. The dressings are removed at the time of operation, and the wound washed carefully, without causing bleeding, with sponges dipped in warm salt solution. The surface is dried thoroughly and a pad of dry gauze placed over the wound; it is pressed down firmly on the granulations, and removed only when the operator is

Fig. 3.—A, the actual size of a small deep graft with its edges curled under. When this graft is pressed down on a wound the edges flatten under, thus making the graft about one-third larger. B, the punched out defects left by cutting the grafts. Some are filling up with blood in spite of the epinephrin in the local anesthetic. Note the depth of the pits and the rim of undisturbed skin between them. C, a close view of an area grafted with small deep grafts. The grafts themselves are of normal-appearing skin, which is soft and flexible. Between the grafts is scar tissue, which is slightly depressed. The scaly appearance of this area is due to desquamation of epithelium. Photograph was taken six months after grafting.

repeated trials from many donors. Autografts on the same wounds healed promptly.

The grafts may be obtained from almost any portion of the skin. It is considerably easier to cut them from a region such as the front of the thigh (where

the skin is quite taut), than where it is lax, as for instance on the abdomen.

The region from which the skin is taken has little, if any, effect on the success or failure of the grafts.

A large number of these grafts can be obtained from a comparatively small area, thus making it possible to use small grafts on extensive wounds without any severe tax on an ill patient.⁶

Preparation of Area from Which the Grafts are Taken.—A satisfactory method of cleaning the skin before removing the grafts is to shave, and then wash thoroughly with green soap and water. Rinse with sterile water and sponge with ether, followed by alcohol; finally rinse with normal salt solution and dry. It is better to use no antiseptic in the preparation of this area, although very satisfactory results follow the use of iodine technic.

Anesthesia.—As these grafts are obtained with little pain and are usually applied to undisturbed granulations, general anesthesia is unnecessary, unless the patient is a young child, or in a highly nervous condition. It is as a rule desirable to inject 1 per cent. quinine and urea hydrochlorid solution, or 0.5 per cent. novocain, with a small amount of epinephrin, and take the grafts from the anesthetized area. The infiltration seems to have no hindering effect on the healing of the grafts.

TECHNIC

The simplest way to obtain these grafts is to pick up a bit of the epidermis with a straight intestinal needle held in an artery clamp⁷ (Fig. 2). It is raised so that a little cone is formed and the base of the cone is cut through by depressing the blade of the knife.⁸ (The thinner Reverdin grafts may be obtained by cutting off the tip of the cone.) The graft, still on the needle, is transferred to the wound, with raw surface downward. The grafts are placed in rows, a space of not more than 5 mm. being left between the grafts.⁹ When two rows are in place, a strip of dry sterile rubber protective about 1.5 cm. wide is applied over them, so that the lower edge of the protective just covers the lower row of grafts. Then the protective is pressed down over the grafts firmly with a gauze pledget, and the edges of the grafts will uncurl and spread out evenly on the wound. The next row of grafts is placed close to the edge of the protective, and after two or three rows are applied, they are covered with a second strip of protective, which overlaps the first piece about one-half its width. The protective is pressed down firmly, and the procedure is continued in this manner until the whole wound, or the part selected, is covered.¹⁰ The ends of the protective strips which extend beyond the wound edges may be fastened securely to the normal skin by means of a

few drops of chloroform.¹¹ Moist salt gauze over the protective strips secured by a bandage is a satisfactory dressing. The part should also be immobilized as far as possible.

The area from which the grafts are taken may be dressed with boric ointment spread on a sheet of rubber protective, which is snugly strapped over the wound, or with silver-foil and dry gauze.

The grafts are either round or irregularly oval. They vary between 2 and 4 mm. in diameter (Fig. 3), and should seldom be larger than 4 mm. They are thickest in the center and taper off toward the edges. With a sharp knife the size, contour and depth can be judged quite accurately.

The wounds left by the removal of the grafts have the appearance of small pits punched in the skin, there being a rim of untouched epithelium between the pits. Fat may be seen in the bottom of some of the pits, which shows that a considerable depth of the skin is used.

Fig. 4.—A, the development of keloid on the thigh in the wounds from which small deep grafts were cut. All of these grafts were cut at one operation. There was no keloid formation around the grafts. Photograph was taken one year later. B, keloid formation around small deep grafts. The grafts, which are soft and in good condition, can be seen at the bottom of little pits. The development of the keloid around the grafts followed a perfectly flat and apparently normal healing. There was no keloid growth in the scars from which the grafts were cut. Photograph was taken nine months after grafting.

There is more bleeding following the removal of these small deep grafts than when the Reverdin grafts are cut, and the resulting scars are also somewhat more pronounced.

Sometimes when the grafts are small, and the skin blood-stained, it is difficult to determine which is the raw surface. This difficulty is obviated when the grafts are obtained from a negro or when iodine technic is employed.

When a large number of these grafts have to be applied the process is very tedious, but this may be mitigated to a certain extent by having two men cutting the grafts, while one man places them, or vice versa.

11. C. A. Porter of Boston uses crape lisse and collodion to hold grafts in place on small wounds.

6. In a number of instances I have applied several hundred of these grafts at a single operation.

7. Agnew, D. H. (Med. and Surg. Rep., 1874, xxxi, 424), first suggested the use of the needle to raise the bit of skin to be cut in obtaining Reverdin grafts.

8. The use of forceps and scissors in obtaining small grafts is not desirable, as the skin is thereby traumatized unnecessarily.

9. The grafts will spread over a considerably larger area, but I believe that more stable healing is produced when the grafts are placed quite close together than when they are planted with greater intervals between.

10. The overlapping strips of protective allow the escape of any secretions from the wound into the overlying dressings.

POSTOPERATIVE TREATMENT

The patient should be kept in bed for a longer or shorter period, depending on the size and location of the grafted area. The part grafted should be immobilized and protected from injury.

The dressings should be removed on the second or third day, and any wound secretions carefully mopped up, or washed off with a gentle irrigation of normal salt solution.

It is possible, even as soon as this, to tell whether or not the grafts have been successful, and in many instances a narrow ring of new epithelial growth can be seen surrounding each graft.

Some bland ointment on old linen is then applied, and if after a day or two the epithelial growth from

with a dry powder, such as zinc stearate, and exposed to the air.

I have not found the open treatment of these grafts just after application to be satisfactory.

The grafted area should be protected from injury for several weeks. Gentle massage is advisable after about three weeks, and should be continued until the grafted area is as freely movable as the normal skin around it.

There is a marked desquamation of the grafted surface when it dries out, especially between the grafts, which is evidently due to epithelial overproduction, but this scaliness can easily be controlled by the application of olive oil or oil of theobroma (butter of cacao).

Fig. 5.—*A*, ulcer, seven months' duration, following a streptococcus infection. *B*, one week after grafting with small deep grafts. Note the close proximity of the grafts to each other. Many of them have grown together and also have joined the stimulated skin edges. Shrinkage in the size of the wound is noticeable. *C*, the same wound two weeks after grafting, entirely healed. *D*, the grafted area two years and three months after operation. The individual grafts can be plainly seen and are sharply differentiated from the surrounding scar tissue.

the grafts is not as vigorous as desired, it is well to alternate the bland ointment with scarlet red, 8 per cent., in petrolatum or zinc ointment, or to use some other epithelial stimulant.

The surface from which the grafts are taken should be dressed in three or four days if protective is used, and the area dusted with a dry powder. If silver-foil is used it should not be disturbed for ten days, after which time all dressings may be removed.

As soon as the new epithelium has filled the gaps between the grafts and joined the epithelium from the wound edges, the grafted area may be dressed

UNTOWARD POSSIBILITIES

There are certain untoward possibilities which must be considered. On account of the simplicity of the operative procedure we are accustomed to regard the use of small grafts as attended with no danger and with but few bad results. Aside from contraction, which may occur, we must consider the danger of carrying infection from the granulating surface to the wounds from which the grafts are cut. It is a difficult matter to convey a graft on a needle, or any other instrument, to a granulating wound without occasionally touching the granulations with the instru-

ment. In order to avoid this chance of contamination it is best either to use a fresh needle for each graft, or to have several needles, so that one can be "flamed" while the other is in use.¹²

Another disagreeable occurrence is the formation of keloid (Fig. 4). Occasionally a massive keloid growth will form in the grafted area, and the grafts themselves can be seen at the bottom of little depressions in the keloid. This keloid growth would probably occur in these wounds whether they were grafted or not. Again, keloid may develop in the scars of the wounds from which the grafts are taken. We know that in certain persons there is a tendency to the development of keloid following almost any wound. This is of course especially true among negroes. It has been my experience that keloid develops in white persons, either in the wound itself or in the areas from which the grafts are taken, much more frequently in burns than in large wounds from other causes. Burns caused by acids seem especially prone to be followed by keloid.

COMMENTS

The age of the patient has apparently little effect on the healing of small grafts. The general health should be carefully looked after and when necessary a vigorous building-up treatment inaugurated. Small grafts will often succeed on granulating surfaces under conditions in which no other type of graft could live. There is almost invariably a marked stimulation of the epithelium of the wound edges following the application of these grafts, even though the grafts be unsuccessful.

The shrinkage in the size of the wound after grafting with small grafts is in some cases quite remarkable. Contraction may occur under a grafted area, but it is not nearly so likely as when grafting is not done. If the grafts are placed close together, contraction may be to a large extent prevented. Healing is very much expedited by the use of these grafts, and resulting cicatrix is solid and resistant.

Small deep grafts are apparently not replaced by scar tissue, as they can be demonstrated as definite areas of normal-appearing skin surrounded by scar tissue even after several years (Fig. 5).

A wound grafted with these small grafts, placed at intervals, has a dotted appearance, and the cosmetic result is not so satisfactory as when either large Ollier-Thiersch, or whole thickness grafts, are used. For this reason it is better not to use them on the face, unless especially indicated. However, if the grafts are placed close together, so as to touch each other, the appearance of the grafted area is very much improved.

A brownish pigment sometimes appears in the grafts themselves, as well as in the cicatrix between them. The scars left by the removal of these grafts is after a time scarcely noticeable, except in those instances in which pigmentation occurs.

The sensation of an area grafted with small deep grafts gradually comes in from the periphery, and not from the underlying tissues.

12. The importance of this point was impressed on me by the following incident: A very resistant ulcer of the groin of long standing, the etiology of which could not be definitely determined, was grafted with small grafts. The wounds from which the grafts were taken on the thigh became infected, and when I was called to see the patient a week afterward, an ulcer similar to that in the groin had developed. This ulcer also resisted every method of treatment used, and it was finally necessary to excise the entire area with a liberal margin. The defect, which was 11 cm. in diameter, and down to the deep fascia, was immediately grafted with a Thiersch graft and healed promptly.

The procedure is by all odds the simplest method of grafting. It requires little preliminary preparation after the granulations are in condition, and unless the area to be grafted is large, the grafting can be done in the patient's room. Enough autografts can be obtained from a small area to cover a large wound without causing any appreciable injury to a patient already in a serious condition.

Several patients have come under my care whose lives have undoubtedly been saved by the successful use of these small grafts.¹³

The difference in the ultimate result between small superficial grafts and small deep grafts placed close together is almost as marked as the difference in results between Ollier-Thiersch grafts and whole thickness grafts.

INTRINSIC CANCER OF THE LARYNX

COMPLETE EXCISION APPARENTLY EFFECTED BY ENDOLARYNGEAL OPERATION

SIR ST. CLAIR THOMSON, M.D.

Professor of Laryngology and Physician for Diseases of the Throat
in King's College Hospital

LONDON, ENGLAND

The treatment of intrinsic cancer of the larynx by laryngofissure is remarkably satisfactory. It is doubtful if the results of operation for cancer in any other part of the body can surpass those which I have already reported.¹ Since giving full particulars and showing cases before the Medical Society of London in 1912, I have continued to obtain the same results; that is, no patient has been lost by operation, and 80 per cent. have remained free from recurrence. This freedom from recurrence dates back in some cases for ten years.

The same proportion of lasting cures was obtained by Semon, who did much to popularize laryngofissure in these cases, and similar records were secured by Butlin, who revived the operation after it had been quite discredited both in this country and abroad. Possibly it is because these excellent results were first obtained in England that we, in this country, have come to look askance at any other route for removing an endolaryngeal cancer except that obtained by splitting the larynx. We are even a little skeptical in accepting the records which claim permanent cures by operating through the mouth; yet reports of such cases have been published by several eminent authorities.²

Among my recent cases it has been my good fortune to obtain, in a curious way, the definite proof that an intrinsic cancer of the larynx can be completely removed *per vias naturales*. But I hasten to add that the completeness of removal was unintentional and that I do not for a single moment suggest that excision

13. I have in mind an illustrative case. A child, aged 12, was severely burned over the pelvis, thighs and legs. She came under my care nearly a year after the accident, during which period she had been repeatedly grafted without success. Her condition was desperate. She was delirious, extremely emaciated and generally depleted by the pain, and by the long-standing suppurating wounds. As a last resort the wounds were grafted with small deep, autografts, which were successful, and within a few days the change in her condition for the better was astonishing. A prompt recovery followed. No other type of autograft could have been successful in this case, on account of the condition of the granulations.

2. Fraenkel, B.: Deutsch. med. Wchnschr., xv, 1; Arch. f. Laryngol., 1897, vi, 361. Arslan: Arch. Ital. di Otol., 1901, xii, Part 2; Ann. des mal. de l'oreille, 1904, xxx, 130. This gives an analysis of recorded cases. In two personal cases, confirmed by the microscope, the patients remained well after four years and twenty months, respectively. Funder: Jour. Laryngol., 1910, xxv, 602.

of a cancer of a vocal cord should ever be confided to the laryngeal forceps. On the contrary, this very case which I am about to relate, gives the strongest proof of the desirability and hopefulness of treating intrinsic laryngeal cancer by opening the larynx from the outside. It was the first case of endolaryngeal cancer which I have handled in a woman; all my other patients were males.

Mrs. A. P., aged 53, had been hoarse for eight months when she was sent to me at King's College Hospital, Oct. 12, 1912, by Dr. Shaw of Great Yarmouth. The right vocal cord from the anterior commissure back to the vocal process was replaced by a reddish, cauliflower growth (Fig. 1). This

Fig. 1.—Intrinsic cancer of the larynx. Epithelioma of the right vocal cord.

somewhat interfered with the movement of the cord, but its intrinsic mobility was not impaired. There were no enlarged glands and the case was evidently a very suitable one for operation by laryngofissure. The Wassermann reaction was negative and the chest was healthy.

As the growth did not infiltrate the cord to any great extent (as shown by the persistence of mobility), and as it projected well above the surface, I decided to remove a portion so as to confirm the diagnosis by microscopic examination. With the aid of cocaine, and using a large-sized duck-billed forceps of Morell Mackenzie, with the indirect method, I seized as large a piece of the cord as possible, and, finding it very tough, I removed it by avulsion. The toughness and naked-eyed appearance were confirmatory of my diagnosis of malignant disease, and the following report on the removed tissue was kindly furnished by Dr. d'Este Emery:

"The material is an irregular mass about 9 by 5 mm. It is divided into two parts, of which one consists of papillomatous and epitheliomatous tissue, with a very small amount of fibrous stroma which shows evidence of subacute inflammatory changes. The large portion consists of a firm fibrous basis. On one edge there are some mucous glands. On the other two unattached edges, there is a margin of epitheliomatous tissue which in places is inflamed and ulcerated.

"The epithelioma in this section is a typical one but shows little keratinization. There are a few imperfectly formed cell-nests, and some so-called 'cancer parasites.'"

Nov. 28, 1912, anesthesia was induced by Dr. Silk by intravenous infusion of ether and hedonal, administered through the internal malleolar vein. The usual laryngofissure operation was carried out; no Hahn's tube was used. The remains of the right cord and the ventricular band were dissected up with their perichondrium from the inner surface of the thyroid cartilage and removed *en masse* together with the vocal process of the arytenoid cartilage. The tracheotomy-tube was removed before the patient left the table. She would have been allowed up the next day, but she was exceedingly drowsy from the hedonal and could hardly be roused. Within forty-eight hours of the operation, however, she was sitting out of bed and eating solid food. She returned to the country a fortnight after operation.³

The tissue removed by laryngofissure was submitted to Dr. Emery, who reported on it as follows:

"The specimen is of an irregular shape, the longest dimensions being 19 by 10 mm. The base consists of striped muscle which is inflamed and edematous; some mucous glands occur in the lowest portion. Above this there is a layer of organizing granulation-tissue in various stages, but there is no epithelial covering. Mucous glands, normal or slightly inflamed, are scattered throughout the section, and at one end there is a triangular piece of cartilage about 2.5 mm. long.

"There is no sign of epithelioma or other malignant disease in any other part of the section."

This report brings us to the instructive conclusions which may be drawn from this case. To be brief, I will simply state them in order.

1. Cancer of the vocal cords, is, in early stages, a very slowly progressive and strictly limited process. (In this case hoarseness dated from eight months, the cord was still quite mobile, and the disease was still superficial.) Alteration of voice is the principal and may be the only symptom. Persistent hoarseness in any patient calls for a definite diagnosis.

2. Diagnosis is based chiefly on inspection of the larynx. Only in certain cases in which the growth is a superficial and not an infiltrating one can it be confirmed by microscopic examination.

3. The growth, even when it occupies almost the entire length of a vocal cord, can sometimes be completely removed by endolaryngeal operation in early cases. But this completeness can be ascertained only when, by laryngofissure, the remains of the vocal cord and adjoining soft parts have been removed and submitted to the pathologist.

4. Laryngofissure is, therefore, the operation of choice in all cases of endolaryngeal cancer.

5. The operation offers the very best prospects, first, because the disease remains for some time superficial and limited, and secondly, because laryngofissure cannot be considered a dangerous operation.

6. Statistical results show a lasting cure in 80 per cent. of cases, and if all patients presented themselves and cases were diagnosed early there is no reason why the results should not be even more satisfactory.

Fig. 2.—Intrinsic cancer of the larynx after operation by laryngofissure, showing a large (innocent) granuloma.

My patient is in good health, with a useful voice, and has had no recurrence at the present date, that is, one and a half years after operation.⁴

I have already confirmed the opinion originally enunciated by Semon that if recurrence does not take place during the first year after operation there is every prospect of permanent cure.

ADDENDA

In addition to the six conclusions tabulated above this case suggests three other interesting points.

4. The patient was shown before the Clinical Congress of American Surgeons, in London, July 28, 1914.

3. The patient was shown before the Clinical Section, Royal Society of Medicine, Feb. 14, 1913.

1. *Regrowth*.—Toward the end of January, 1913, that is, two months after operation, the patient began to show symptoms of what many would have taken to be a recurrence of the growth (Fig. 2). But I had no anxiety myself, partly on account of the foregoing negative report from the pathologist, but chiefly from experience with previous cases in which a regrowth during the first two months nearly always proved to be a simple granuloma. In this case the fresh neoplasm was removed entire through the mouth with the same Mackenzie forceps, and by indirect laryngoscopy, and was found to consist of simple granulation-tissue, showing no epithelioma or sign of malignant disease in any part of the section.

The moral of this is, that a regrowth in early days after a thyrotomy for cancer is not necessarily malignant.

2. *Value of Indirect Laryngoscopy*.—The case shows that a considerable growth, indeed, practically an entire vocal cord, can be removed with one bite of the forceps used by the indirect, or, as some already call it, the "old method" of laryngoscopy. As I have practiced Killian's direct laryngoscopy for eleven years, I feel equally skilled with the two methods, and each method has its own well-marked indications. I very much doubt if the most expert endoscopist could have removed as large a growth as I did in this case, and certainly it could not have been done more quickly or less disagreeably. The indirect method allows of the forceps being sloped to the opposite side of the body, so that any growth on a cord can be more cleanly and completely seized than is possible with the limited action of cutting forceps working in a circumscribed, circular tube. The importance of removing as large and intact a portion of growth as is possible is of the highest value when it is desirable to submit a suspected neoplasm to the microscope. It will be a loss to laryngoscopy, and to our patients, if the rising generation of throat surgeons neglect to acquire the gentler art of indirect laryngoscopy and limit themselves to the easier but rougher technic of direct examination.

3. *Anesthesia*.—Laryngofissure can be well carried out under local anesthesia. I have employed it in one successful case, but I doubt if many of our sensitive patients in this country would submit to the moral ordeal. In the foregoing case the operation lasted eighty-five minutes. Anesthesia was induced by a mixture of 1 ounce of ether and 20 grains of hedonal to a pint of normal saline solution, the object of the hedonal being to diminish as far as possible the total amount of fluid passed into the circulation. Two pints and 6 ounces of this mixture were used, corresponding to 2 ounces $2\frac{1}{2}$ drams of ether and 46 grains of hedonal, including a certain amount of wastage. Probably 2 ounces of ether and 40 grains of hedonal were infused through the internal malleolar vein. As administered by Dr. J. F. W. Silk, the resulting anesthesia was, from the operator's point of view, perfectly ideal. The field of operation was quite clear of the anesthetist and his paraphernalia, and the patient's sleep was tranquil and even.

But the profound sleep in which she continued to be plunged next day gave me some anxiety. For twenty-four hours it was difficult to arouse her, and I thought what a serious condition might have arisen if, peradventure, she had inspired any blood during the operation and we had wished her to cough up the resulting bronchial or pulmonary catarrh.

I would suggest that in future cases the hedonal be reduced to a minimum, if it cannot be dispensed with.

In another case I had there was some thrombosis of the lower part of the internal saphena vein, and this kept the patient in bed when he ought to have been up and about.

Besides, I am not quite sure whether it is wise to flood the circulation with over 2 pints of liquid, and it is difficult to keep within the limit unless some such drug as hedonal be employed with the corresponding tendency to prolonged and profound after-sleep.

Anyhow, the method of anesthesia by intravenous infusion of ether has not yet established itself in my opinion, for these cases, and it still requires consideration. In my more recent cases I have returned with satisfaction to the use of chloroform employed in the usual way.

64 Wilapole Street, W.

SARCOID OF BOECK *

S. E. SWEITZER, M.D.

Assistant Professor of Dermatology, University of Minnesota

MINNEAPOLIS

Kaposi¹ first grouped mycosis fungoides, lymphoderma perniciosus, sarcomatosis cutis and the real sarcomas of the skin in a class which he called sarcoïd. Spiegler² and Max Joseph³ did some early work on the subject. Fendt⁴ classed as sarcoïd, "tumors of benign prognosis, having only a limited growth, frequently healing with arsenic, composed of groups of round cells, which are circumscribed, divided by septa and encapsulated."

Boeck⁵ in 1899 reported as multiple benign sarcoïd a new disease of characteristic clinical and histologic appearance. In later articles Boeck⁶ reported a series of cases and added a new type of the disease, the diffuse infiltrating type.

The work of Boeck caused many cases to be reported in the European literature but in America the only cases are those of Gottheil,⁷ Pollitzer⁸ and Sutton.⁹ G. H. Fox and Wile¹⁰ reported an atypical case and Howard Fox¹¹ reported one composed histologically of round cells, so that it is not a sarcoïd of Boeck. Darier and Roussy¹² in 1904 described a subcutaneous sarcoïd closely resembling Boeck's sarcoïd. Darier¹³ in 1910 made an extensive study of the entire group of sarcoïds. He divided the group into four types, as follows:

1. Multiple benign sarcoïd of Boeck.
2. Subcutaneous sarcoïd of Darier-Roussy.
3. Erythema induratum-like sarcoïd of the extremities.

4. Spiegler-Fendt type. Non-tuberculous, composed of round cells. Resembles neoplastic lymphoderma.

Boeck's sarcoid or miliary lupoid, as he later called it, has three forms: (1) large nodular; (2) small nodular or papular; (3) diffuse infiltrating. The lesions may vary in number from one only, as in the

the urine and blood are normal. It occurs more often in women than in men (Fox and Wile¹⁰). It may occur, according to Boeck, from the thirteenth to the forty-fifth year, but cases have been reported earlier (Sutton⁹ and later Mazza¹⁹). Rather typical in the disease is the involution of the nodules under prolonged arsenical medication.

The histologic picture is characteristic. "One look in the microscope suffices to make a diagnosis," according to Darier.¹⁵ Sections show sharply circumscribed, deep-seated nodules, separated by connective-tissue septa which seem to have been pushed aside by the growing tumor. The cells are epithelioid with pale-staining nuclei. At the edges are seen a few lymphocytes, giant-cells and rarely giant-cells of the true Langhans type.

The elastic tissue is absent in the nodules but present in the septa. There are no leukocytes present, as a rule, and there is never any evidence of caseation. Blood-vessels can be seen in the nodules.

The Darier-Roussy type of subcutaneous sarcoid is very rare. Three cases were recorded by Darier in 1910. They consist of round or oval subcutaneous nodules from the size of a hazelnut to a walnut. They are few and are located on the back of the trunk. There is no tendency to ulceration and no influence on the general system. Histologically they are situated in the subcutis, composed of epithelioid-cells and new connective-tissue cells and lymphocytes; numerous giant-cells are seen and a few plasma-cells, mast-cells and leukocytes. It differs from Boeck's in its appearance, its size, its subcutaneous location, and also looks

Fig. 1.—Sarcoid of Boeck.

cases of Kreibich and Kraus¹⁴ and Urban,¹⁵ or run into many thousands, as in the case of Hallopeau and Eck.¹⁶ It is located on the face, back, shoulders and extensor surfaces of the arms, but can occur on the scalp and lower extremities. Boeck asserted that the soles of the feet were not involved. Wolfheim¹⁷ reported a case where the soles were involved.

It may begin suddenly with a diffuse edematous reddening and after from eight to fourteen days disappear and leave one or more circumscribed infiltrated areas. More often it begins as a little round nodule, deep in the cutis and as it approaches the epidermis lifts it up. The nodules grow very slowly, come out in crops and last months and even years. They feel larger than they look, according to Unna.¹⁸ They are red at first, later red-violet, then yellowish and finally brownish. They feel hard, and often, on pressure with glass, show minute yellow foci. This led to the name "miliary lupoid." This is seen at the time of retrogression. As retrogression occurs the nodules become depressed in the center and a fine network of telangiectatic vessels run over the edge; sometimes a fine scale forms. The nodule or papule may completely disappear and leave a pigmented spot or an atrophic scar with telangiectatic vessels over it. It never softens or ulcerates. The mucous membrane is sometimes affected. The lymphatic glands may or may not be enlarged. The general condition is not influenced by the disease, and

Fig. 2.—Enlargement showing individual lesions.

more tuberculous. It is less sharply defined and more infiltrating.

The third group of Darier, the sarcoid of the extremities resembling erythema induratum, is more frequent, and occurs mostly in women. It consists of nodules with circumscribed thickening and hardening of the

cutis and subcutis. They are painless, seldom soften and ulcerate and are generally located on the extensor surfaces of the extremities. They are from the size of a pea to that of a hazelnut.

Pelagatti,²⁰ Thibierge and Bord²¹ and Darier himself reported cases of this type. Many authors look on this as erythema induratum on account of the occasional ulceration, positive tuberculin reaction and the few cases of Carle,²² Thibierge and Ravaut,²³ Colcott Fox²⁴ and Schidachi,²⁵ in which tuberculosis was demonstrated in inoculated animals. Philippson²⁶ demonstrated tubercle bacilli in the sections.

The fourth type, or sarcoid of Spiegler-Fendt, shows no relationship to tuberculosis, but is composed of round cells and is probably related to the neoplastic lymphoderma. This type shows nodules in the cutis, the skin is rose, lilac or dark red in color. It is located on the body, is chronic in course and has no tendency to ulceration. It is usually affected by arsenical medication. Histologically the lesions are composed of

cases reported by Darier-Roussy and one of his own are the only cases reported so far of Type 2, and questions if this type really does not belong to erythema induratum. Volk reports a case of subcutaneous sarcoid in which he obtained the tubercle bacillus in a guinea-pig and produced tuberculous iritis in rabbits' eyes.

Fig. 4.—Section of tumor under very low magnification; E, epidermis.

REPORT OF CASE

The following case of Boeck's sarcoid came under my observation early in 1914. The patient was sent into the University Hospital by Dr. A. W. Shaw of Buhl, Minn., being referred to me by Dr. F. R. Wright.

Patient.—Mrs. H. G., Swedish, aged 53; large and well nourished. Weight 169. Eruption began three years ago, first being manifest in the scalp, then the face was affected and finally the back and arms.

Macroscopic Examination.—The scalp shows no new lesions but eight areas of irregular shape and size, somewhat depressed and slightly scaly. The face and forehead show

Fig. 5.—Portion of lower part of tumor under higher magnification.

Fig. 3.—Back showing depressed areas.

round cells more or less circumscribed and sometimes encapsulated. Epithelioid and giant-cells are either absent or very scanty. Probably many cases of sarcoma of the skin reported as cured belong to this group.

In regard to Darier's classification, Nobl²⁷ asserts that the subcutaneous sarcoid and erythema induratum are identical. Volk²⁸ in a recent article says that Type 4 can be dropped, as this class belongs to the neoplastic lymphoderma. Type 3, Volk, in agreement with others, classes as erythema induratum. This leaves only Types 1 and 2, and he asserts that the

about thirty lesions, some new, some old. They begin as a small, round, freely movable tumor deep in the skin and eventually involve the epidermis, lifting it up in a nodule, red at first, later red-violet, and as they get older more of a brownish-yellow. Finally the nodule becomes depressed in the center and shows a small white scale. Over the edges of many of the old lesions is a fine network of telangiectatic vessels. These old lesions are some small singular ones of the size of a grain of wheat and others seem to be formed of

a group of these small lesions and are therefore polycyclic in shape. At the nasolabial fold are a few younger lesions lighter in color and not depressed. There is no evidence of any pus or caseation in any of these lesions. On pressure with a glass it is possible to make out minute round yellowish foci. On the back there are about fifty lesions, most of them evidently having undergone resolution. The new ones start as round hard nodules very deep in the subcutaneous fat. As they grow older they flatten out and lift up the epidermis in a hard, firm, elevated, flat brownish-red lesion. Evidently an atrophy finally takes place and the lesions heal, leaving a soft depressed bluish area, covered with dilated capillaries. There are no scales present on the back. The breast and upper arms show a few isolated lesions, one or two of which show a fine

separated by connective-tissue septa. The cells of the tumor were epithelioid with pale-staining nuclei. A few lymphocytes were seen at the edges. In the tumor from the back were giant-cells of the true Langhans type. Elastic tissue was absent from the tumor but present in the septa. No tubercle bacilli were found in any of the sections and no evidence of caseation or necrosis was seen.

Fig. 8.—Langhans type of giant-cell.

Figs. 6 and 7.—Still higher magnification of tumor.

scale. The mucous membrane of the nose and mouth is not involved. The glands are not enlarged.

Two subcutaneous injections of tuberculin gave no local or general reaction. Wassermann reaction was negative. Blood and urine normal. A small section was cut from a lesion on the face for microscopic study. Two large pieces were cut from the back to obtain more material for histologic study and animal and cultural experiments.

Microscopic Examination.—Histologically the tumors on the face and back were identical with the exception that the one from the back showed more giant-cells. The epidermis was normal. The papillary layer was unchanged except where the tumor encroached on it in some sections; there it was flattened a little. The tumor was situated deep in the dermis and consisted of a number of round or rounded areas

Animal Experiments.—Two rabbits and four guinea-pigs were inoculated intraperitoneally with pieces of tissue from the tumor. One guinea-pig which died of some intercurrent disease ten weeks after inoculation showed at post-mortem several small firm nodules in the omentum. No parasitic diseases were found to account for these nodules. Examined microscopically the structure strongly suggests healed tubercles. While these lesions cannot be taken as positive proof of healed tuberculosis they are best explained by this interpretation. They are about the type of lesions one would expect to see as the result of infection with tubercle bacilli of

Fig. 9.—Epithelioid cells highly magnified.

low virulence. All the ordinary media were inoculated with material from the tumor on the back. No growth was obtained either aerobically or anaerobically.

ETIOLOGY

The etiology of Boeck's sarcoid is of interest. Boeck himself thought it to be an infectious bacillary dis-

SARCOID OF BOECK—SIVEITZER

995

DIAGNOSIS AND PROGNOSIS

A clinical diagnosis must always be confirmed by the microscope. Clinically, leprosy, lupus vulgaris, lupus erythematosus, leukemia cutis, syphilis, erythema induratum and lupus pernio must all be considered. The prognosis as regards life is good. Recurrences are common, however.

Therapeutically arsenic has given good results in many cases. My patient has, according to a recent letter, improved very much while taking Fowler's solution. Darier has recommended calomel and tuberculin.

The histologic work in this case was done by Dr. E. T. Bell, assistant professor of pathology in the University of

case which is identical or closely allied to tuberculosis. Darier classed it as a tuberculid. Winkler²⁹ analyzed seventeen cases and found that six patients had sure signs of tuberculosis, seven had swollen glands and four no signs of tuberculosis at all. Darier, Kreibich and Kraus, Opificius³⁰ and Stimpke³¹ had cases in which a local reaction was produced by tuberculin. Kren and Weidenfeld³² inoculated twelve guinea-pigs and had no successful results and none of the guinea-pigs reacted to tuberculin given one or two months later. Morawetz³³ in 1909 reported a case of Boeck's sarcoid in which Boeck personally confirmed the diagnosis. There was no local or general reaction to tuberculin. A guinea-pig inoculated, however, was dead in ten days from tuberculosis and tubercle bacilli were recovered. Kyrle³⁴ in 1910 reported a case of Boeck's sarcoid in which animal inoculation was successful in one guinea-pig after ten months. Kyrle³⁵ even goes so far as to suggest the name of tuberculosis cutis typus Boeck, considering all cases of Boeck's sarcoid as due to tubercle bacilli. Pohlmann³⁶ inclines to the belief in the tuberculous nature of the disease. Oppenheim³⁷ in 1913 reported three cases of tumors deep in the skin. These tumors appeared after hypodermic injections and gave a histologic picture that was identical with sarcoid of Boeck. He thinks that not all cases of sarcoid are due to tuberculosis but that some other organism may occasionally cause it. Urban³⁸ agrees with Kreibich and Kraus¹⁴ in considering that there are two varieties of the disease, one related to tuberculosis, the other group having nothing whatever to do with it. Kren³⁸ in a recent communication considers Boeck's sarcoid a tuberculosis of low virulence, but says that as yet this view has not been generally accepted in the literature. With regard to the scant

Minnesota, the animal experiments were done by Dr. W. P. Larson, assistant professor of bacteriology of the University of Minnesota, to both of whom I am indebted for kindly aid and advice.

625 Syndicate Building.

ABSTRACT OF DISCUSSION

DR. HOWARD FOX, New York: I have had an opportunity to study a case of this affection reported by my father, Dr. George Henry Fox, in conjunction with Dr. Udo J. Wile, as well as one of my own published last year in the *Journal of Cutaneous Diseases*. In my case it was practically impossible to arrive at a positive diagnosis, as the patient, a young lady, refused to have a biopsy performed. The nearest approach to a diagnosis, after the patient had been seen by many of the best dermatologists in New York and Philadelphia was that it was an atypical case of lupus vulgaris. As a result she was treated with a Finsen-Reyn lamp, operated by a skilled graduate of the Finsen Institute, for a total of about a hundred and fifty hours. After this treatment the eruption on one side of the face almost entirely disappeared, leaving, however, a marked depression. The other side of the face proved entirely refractory to the Finsen therapy and was later treated by Dr. Fred Wise with carbon dioxide snow. This was followed by a complete disappearance of the lesions with a perfect cosmetic result. As a result of this experience I would certainly urge the use of carbon dioxide snow for the treatment of other cases of sarcoid.

DR. F. W. CREGOR, Indianapolis: I report a case which I regarded as one of sarcoma cutis, basing this diagnosis on the picture of a similar case presented by Ehrmann in Vienna three years ago. My patient was a bachelor, 46 years old, who at the age of 11 first noticed dark-red, oval elevations, varying in size from a split pea to a large hazel-nut. The color of the lesions ranged from dark-red to bluish-black, with sharply defined lines of demarcation, and the

Fig. 10.—Tumor produced in omentum of guinea-pig.

results of so many investigators on inoculation of guinea-pigs, it is true that a bacterium of low virulence often may not take in a guinea-pig and at times may take and later become fibrosed as apparently happened in my case.

elevations were at all times very perceptible, and always rising gradually. The patient consulted many physicians, none of whom ever ventured a diagnosis. The family history was negative for any skin disease, and there was no personal history of syphilis or tuberculosis, nor did a careful examination reveal any clinical evidence of either of these diseases. The patient said he had long ago learned that by making an incision into these elevations with his pen-knife, they would rapidly disappear, leaving a smooth, pigmented spot. The privilege of a biopsy has not been granted, but it is promised in the near future, when I hope to make some further studies in connection with this interesting case.

DR. S. E. SWEITZER, Minneapolis: I wish to lay particular emphasis on the etiology of this condition. The conflicting views that have been held are gradually clearing up, and there are types of scroloid that are probably a form of tuberculosis of the skin, as my case shows. The case mentioned by Dr. Howard Fox may have had an entirely different etiology.

NEURASTHENIA AND TUBERCULOSIS (CONCEALED)*

GEORGE DOUGLAS HEAD, B.S., M.D.

Associate Professor of Medicine, University of Minnesota, Medical School

MINNEAPOLIS

Neurasthenia is defined as a condition of exhaustion in the general nervous system. No clear-cut symptom type has ever been described which could identify it and separate it from other diseases, the pathology and etiology of which are known. No specific cause or definite lesion in the brain, spinal cord, peripheral nerves or other organs or tissues of the body have been discovered which would serve to establish a definite pathology for it and thus distinguish it from other diseases the pathology of which is known.

Resting on no etiologic, pathologic or distinctly clinical foundation, the question may pertinently be asked—why does neurasthenia still retain its place as a clinical entity and why do clinicians persist in making the diagnosis of neurasthenia?

Because after the cases of recognizable organic disease simulating neurasthenia have been excluded from the group, a good number remain in which clinicians can detect no tuberculosis, no syphilis, no gastric ulcer, no nephritis, no organic heart-disease, no exophthalmic goiter or other organic disease.

That the limitations of our diagnostic resources may be responsible for this is quite probable because the Wassermann reaction has helped to exclude from the group of so-called neurasthenias many cases of concealed lues; the Roentgen ray has subtracted a number by revealing the presence of unrecognized gastric ulcers, and the more recent methods of cardiac examination and diagnosis have taken out a not inconsiderable number of cases of organic heart-disease.

If it can be shown that many of the so-called pure neurasthenias harbor a tuberculous infection so concealed as to have hitherto escaped recognition, the death knell of neurasthenia as a clinical entity must be sounded.

The close relationship between neurasthenia (so-called) and tuberculosis has long been recognized and commented on.

* Read before the Section on Practice of Medicine at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

* Because of lack of space this article is abbreviated in THE JOURNAL. The complete article appears in the Transactions of the Section and in the author's reprints.

Stiller¹ devotes a whole chapter to the subject.

Lawrason Brown has emphasized the fact that in no disease is the neurasthenic state so frequently encountered as in tuberculosis.

It is not my intention to discuss the relationship between neurasthenia and clinically demonstrable tuberculosis, nor do I intend to consider the cases of clinically recognizable tuberculosis exhibiting neurasthenic symptoms.

The purpose of this study is to present evidence to prove that:

1. Many cases of clinically pure neurasthenia harbor tuberculous lesions so concealed as to escape detection by the examination methods usually employed.

2. No organic disease except tuberculosis can be discovered in these cases.

3. The diagnosis of tuberculosis rather than neurasthenia should be made in these cases.

4. The nervous symptoms exhibited by these patients should be interpreted as a new clinical symptom type for tuberculosis produced by the toxin of the tubercle bacillus.

In proof of this contention I here present the clinical reports of fifteen cases.

The diagnosis of neurasthenia was primarily made in all. The varied subjective symptoms, the long time over which these symptoms had been complained of, the absence of detectable organic lesions, the build and nervous construction of these individuals seemed to justify this conclusion.

The diagnosis of tuberculosis could not have been made in these cases on the usual symptoms and physical signs of this disease because these were absent.

These patients had no cough (with two or three exceptions), little or no fever, no night sweats, no hemophthisis, no rapid loss in weight, no sputum—hence no tubercle bacilli in sputum.

The presence of a tuberculous lesion in these cases was determined on, first, by a positive reaction to a subcutaneous injection of tuberculin. All the cases except one were injected and gave a positive reaction. In this case (Case 15) tubercle bacilli were subsequently found in the sputum. Second, a history of exposure to an open case of tuberculosis (nine of the fifteen gave this history). Third, doubtful lung signs not sufficient in themselves to establish the diagnosis but valuable as corroborative evidence (six of the fifteen cases gave these).

Roentgen-ray chest examinations were made in six of the cases; in four the roentgenologist reported positive findings in the lungs, in two negative. In one of the cases (Case 12) the roentgenologist reported a healed lesion. The patient, however, gave a positive reaction to tuberculin. In a second case (Case 11) the roentgenologist was in doubt ("diagnosis indeterminate: possible very early incipient tuberculosis"). Yet the patient reacted to tuberculin.

CLINICAL SYMPTOMS

The clinical symptoms of which the patients complained were varied and failed to conform to the symptomatology of any known organic disease. The non-conformity of the symptom complex is a characteristic feature of the cases. Hence the usual diagnosis of neurasthenia.

Named in the order of their frequency they are indigestion (10 cases), headache (9), constipation (7), loss in weight (7), cold hands and feet (6), men-

1. Stiller: Die Asthenische Konstitutionskrankheit.

tal depression (6), crying spells (5), physical tire (5), neckache (5), backache (5), general weakness (5), mental tire (5), worrying over trifles (4), eyeache (4), dysmenorrhea (4), insomnia (3), pains in the chest (2), voice tire (2), dizziness (2), tendency to take deep breaths (2), clearing of throat (2), palpitation of heart (1), shortness of breath (1), fainting spells (1), jerking of limbs (1). Only four had cough and in only one of these was there sputum coughed up.

A careful study of the symptoms complained of gives one no help in differentiating these cases from so-called neurasthenia. The symptom complex they present is the symptom complex described by all writers for so-called neurasthenia. It is the symptom complex diagnosed by all clinicians as neurasthenia. It is so-called neurasthenia.

DURATION OF SYMPTOMS

The symptoms in this group of cases were suffered from over a long period of time. The duration of complaints is measured in years rather than months or weeks.

Five were sickly from childhood. Three complained of symptoms five years or over; four from one to two years, while only three of the fifteen dated their complaints back less than one year.

These patients apparently possess a high resistance against the tubercle bacillus: a relative immunity given to them by tuberculous ancestors or by an infection contracted in childhood which the cell forces of the body have reduced to a quiescent state. If this were not so there would be more active recognizable tuberculosis and less so-called neurasthenia.

In many of them the tuberculous process never becomes very active; the bacilli are probably finally killed out and the individual in later life comes into a fair degree of health.

In some active symptoms and signs appear only after years of suffering from the slow fires of a low-grade tuberculous toxemia often interpreted as neurasthenia (Case 15).

PHYSICAL FINDINGS

The physical examination of these patients revealed little or no positive evidence of organic disease.

In none was a positive clinical diagnosis of tuberculosis made. A searching examination of the chest and other organs was negative for tuberculosis or other organic disease in nine of the fifteen cases.

In the remaining six, doubtful physical signs in the chest were present; but in none of these were the findings fixed and definite enough to establish a diagnosis of tuberculosis beyond a reasonable doubt, even after weeks of observation.

In the majority of these patients the tuberculous process will go unrecognized or diagnosed as (so-called) neurasthenia if the clinician relies on the knowledge furnished him by physical examination alone.

PHYSICAL BUILD

Eleven of the individuals in this group were tall and slender. They had prominent, angular features; high cheek bones; long chests; long, flat or scaphoid abdomens, and slender arms and legs. Two were short of stature but slender build. Two others were of short, chunky build with round faces, broad full chests and short rounded abdomens, and short extremities.

All were of high-strung nervous temperament. All those (seven) in which the position of the abdominal organs was determined showed enteroptosis. Thirteen of the fifteen cases therefore conform to the physical construction of the "habitus phthisicus."

Stiller expresses the relationship between "habitus phthisicus" and "habitus asthenicus" in these words: "There is no doubt to my mind that the habitus phthisicus and habitus enteroptoticus are not only strikingly similar to each other but also are completely identical." This study tends to confirm his conception.

TEMPERATURE

Ten of the group showed at times slight rises in temperature (99.2 to 99.4) usually in the afternoon with a subnormal morning temperature of (97 to 98.2). (Temperature records were taken with patients in bed.)

The afternoon rise would usually occur only occasionally, patients often going for days with no rise above normal. The subnormal morning temperature was more regular, most of the cases showing it day after day.

If these patients are up and about, however, they usually run a temperature of 99.2 to 100 under physical exertion or mental excitement.

These occasional temperature rises in persons with so-called neurasthenia are of great significance. They are often the only tangible clinical evidence of a concealed tuberculous lesion.

In this connection it is interesting to note that in Weir Mitchell's "Fat and Blood," every case reported by him (eight in all) in which systematic temperature records are given had fever (99.2 to 101.2).

PULSE-RATE

The pulse-rate in this group is characterized by its variability and its tendency to rise above the normal. The maximum was usually 100, the minimum about 70. In three cases the pulse-rate ran between 100 and 120. In two the minimum was as low as 60.

A variable pulse-rate is encountered in so many other organic conditions that its value from a diagnostic point of view is doubtful.

If, therefore, one were to draft a clinical picture of this condition with which we are dealing he would describe it as follows:

A person usually under 25 years of age with or often without a history of known exposure to tuberculosis comes complaining of a varied lot of symptoms expressing nervous and physical exhaustion, the most common of which are indigestion, headache, constipation, mental depression, cold hands and feet, backache, neckache, eyeache, crying spells, chilliness, loss of weight, etc. These symptoms have dated back over a number of years with periods of improvement followed by relapse under unusual nervous or physical strain. Partial or complete breakdown often results. On inspection one notes a poorly nourished, high-strung person with angular features, high cheek bones, long chest and abdomen, slender arms and legs and active reflexes.

A careful physical examination reveals no positive evidence of organic disease. Enteroptosis is usually present. Doubtful lung signs are occasionally encountered. The pulse-rate is usually increased; the tem-

2. Es ist mir unzweifelhaft dass der habitus phthisicus und enteroptoticus nicht nur einander auffallend ähnlich sondern ganz und gar identisch sind.

perature record shows an occasional afternoon rise to from 99.2 to 99.4 or more. The laboratory findings are negative for organic disease.

The clinician is puzzled; the long history, the build and nervous construction of the individual, the absence of the signs of organic disease leads to the diagnosis of neurasthenia (so-called). But what is this disease called neurasthenia? Will some one please answer?

Are these patients negative for organic disease? I have given the historical summaries of fifteen in which the evidence is positive that a tuberculous infection exists. It is an active tuberculous process because I do not believe that any one will be so foolish as to argue that a positive reaction to a subcutaneous injection of tuberculin means anything less than an active tuberculous process somewhere in the individual giving that reaction.

The location of the lesion whether it be in the lungs, lymph-glands, peritoneum, bones, or wherever it may be focused need not concern us at present.

The fact stands out that in many of these individuals whom we have been considering negative for organic disease the evidence is incontrovertible that an active tuberculous infection does exist. Are we justified in taking the view that these symptoms of (so-called) neurasthenia are a clinical expression of such an infection? I think we are.

First, because we have no evidence to prove that these individuals harbor any other organic disease except tuberculosis.

Second, because we have good evidence for believing that tuberculosis is a chronic disease often contracted in childhood and remaining in the body in a semiquiescent state for years. The long history of many of these cases can thus be accounted for.

Third, because tuberculosis is the one chronic disease which gives most typically the symptoms of nervous and physical exhaustion encountered in neurasthenia (so-called).

Fourth, because we know that the tubercle bacillus produces a toxin (tuberculin) which circulates in the blood and is capable of producing for years a low-grade toxemia with all its varied clinical expressions.

Every experienced clinician marvels at the varied symptomatology of his recognized cases of tuberculosis, to say nothing of the clinical manifestation of those not recognized.

Are the cases presented patients with neurasthenia harboring an associated tuberculous process? I think not. If some one will demonstrate a pathologic base for neurasthenia so that it can be identified and differentiated from other diseases of known pathology, discussion on this phase of the subject might be profitably continued. In the absence of such pathologic lesions and with reliable proof of the existence in these individuals of a tuberculous process and of this only, it is only reasonable to conclude that an infection is present which is common and about which we know a great deal rather than with a name given to a symptom complex about which we know nothing.

A further question immediately presents itself. What proportion of the cases diagnosed as neurasthenia in which a careful physical examination reveals no tuberculosis, no lues, no nephritis, no exophthalmic goiter, no gastric ulcer or any other recognizable organic disease, shows evidence of a concealed tuberculous infection? I have not as yet sufficient clinical data at hand to answer this question. In my experi-

ence, after excluding all other organic diseases, the number of persons exhibiting the symptoms of so-called neurasthenia failing to react to a maximum dose of a subcutaneous injection of tuberculin is small.

But is it not probable that if one were to select a given number of individuals and subject them to the subcutaneous tuberculin test as large a proportion would react as have reacted in this series of cases?

To this question I answer: No. In between 500 and 600 individuals with symptoms suggestive of a tuberculous infection whom I have injected with tuberculin for diagnostic purposes during the last twenty years, not more than 55 per cent. have given a positive reaction.

I have presented no distinctly pathologic proof that a tuberculous lesion exists in these individuals. This is impossible. These patients are living. They may not die for years. When they do die and are examined of what value is the evidence? If a tuberculous lesion were present at necropsy how could one know whether it existed at the time the individual complained of his symptoms. If a tuberculous lesion is present and healed how can one know whether it was healed at the time of the patient's illness. It is present and active how can one know whether the lesion was present and active at the time the patient complained of his nervous and physical exhaustion?

Post-mortem evidence has proved the reliability of the subcutaneous tuberculin test, and farther than this need not be called up in settling the question under consideration.

Nor can one rest his proof on the later development of recognizable tuberculous lesions. Some of these patients have already developed clinical evidence of the infection. Most of them have not and probably never will develop clinical tuberculosis as it is now understood.

The lesion is too minute, too well walled off, the bacilli are not virulent enough, or the resistance of the individual is too high.

It is for this very reason that so many of these cases are overlooked. It is for this very reason that the diagnosis of neurasthenia has so often been made.

Nor can the proof rest on the presence of tubercle bacilli in the sputum or other excreta. Most of these patients had no cough, hence no sputum and no tubercle bacilli in sputum.

A positive von Pirquet test was present in all but one case (Case 8). But a positive von Pirquet test can not be depended on to detect an active tuberculous infection. In this connection Case 8 is of interest. The von Pirquet test was negative while the subcutaneous test was positive. In my experience with between 500 and 600 injections of tuberculin for diagnostic purposes, I have met a number of cases in which the von Pirquet test was negative while the subcutaneous tuberculin test was positive. I shall make these cases a subject for a later study.

The stereoscopic Roentgen studies of the chest in the hands of an expert can be made of assistance in detecting some of these cases, but cannot be relied on in determining the broad question whether an active tuberculous process exists in these individuals.

The recognition of an active tuberculous infection in these cases must therefore rest primarily on a specific test (for this purpose I have used a subcutaneous injection of tuberculin), and secondarily on corroborative evidence such as a history of exposure to tuber-

NEURASTHENIA AND TUBERCULOSIS—HEAD

culosis, or the presence of suggestive clinical evidence in the lungs, lymph-glands or elsewhere in the body. I have here presented evidence, which it seems to me is conclusive to prove that:

1. Many individuals exhibiting the symptom syndrome of so-called neurasthenia harbor a tuberculous infection and this only.
2. The tuberculous process in most cases is so concealed as to escape detection by the usual clinical examination methods employed, and a specific test must be used to reveal its presence.
3. In the light of this evidence these cases should be diagnosed as tuberculosis and not neurasthenia.
4. We should recognize and adopt a new clinical symptom type for concealed tuberculosis.
5. This symptom type is the symptom complex now recognized by clinicians the world over as neurasthenia.

abandoned and the diagnosis made of tuberculosis (concealed), focus not determined, with chronic tuberculous toxemia exhibiting so-called neurasthenic symptoms.

CASE 2.—Mrs. J., aged 37, married, one child. Family history negative for tuberculosis. Personal history negative except a miscarriage one year ago. Patient has been a healthy woman until one year ago when, following her carriage, she began losing in strength and weight. Contracted la grippe about nine months ago which left her with a slight clearing of throat which continued for two months or more. This disappeared during the summer but reappeared again in the fall. No sputum coughed up. For the last three months has felt nervous and miserable; everything no matter how trifling seems like a mountain to her; she cries at the slightest provocation; is despondent and blue. The slightest exertion, mental or physical, tires her and she has had to give up all her social duties and home cares. Is bothered much with aching in the back of neck. Has had her eyes fitted repeatedly for glasses to relieve her headaches. Has cold hands and feet. Has lost 10 pounds in the last six months. Patient had been carefully examined by different physicians who told her she was nervous and should take a rest cure.

Patient is a short, stockily-built woman, with broad chest and short abdomen, dark hair and eyes. Mucous membranes rather pale. Well-nourished. Weeps during examination. Pupils react promptly to light and accommodation. Kneec jerks active. Marked tremor of eyelids with eyes closed. Active dermatographia. No exophthalmos. No von Graefe's sign. Some tremor of finger-tips. A searching physical examination was negative for organic diseases except that in the lower right chest anteriorly over the fourth and fifth interspaces a fine pleural friction-rub could be heard. Repeated examinations always disclosed the friction-rub in this area.

Urine and blood examinations negative. Wassermann reaction negative. Von Pirquet test positive. Not being able to make a positive diagnosis the patient was given 1/2 c.c. of Bureau tuberculin and gave a positive tuberculin reaction (temperature 100.4) within eighteen hours after injection was given. No Roentgen examination of chest made. The diagnosis of neurasthenia was then abandoned. The friction-rub in right chest and the positive tuberculin reaction justified the diagnosis of tuberculosis of right pleura; chronic tuberculous toxemia exhibiting symptoms of so-called neurasthenia.

CASE 3.—Mrs. L. W. B., aged 30, married, no children. Family history negative except one brother dead of tuberculosis. Personal history negative except childhood diseases. Well as a young woman, never had been sick. Married three years and has been occupied with her husband (a college professor) in teaching work.

About one year ago began running down in weight. At that time was spending many hours in the classroom and doing much outside church and social work. Became blue and depressed; cried easily and on slightest provocation. Was tired all the time and could not get enough sleep. Had an aching pain in back of neck, especially when tired. Had headaches. Lost her appetite. Chilled easily; hard to keep her hands and feet warm. Had a slight cough, especially when using her voice much. No sputum. Hoarsed up easily after talking. Had no fever, no night sweats. Became so nervous and worn out that she had to stop teaching. Consulted various physicians who told her she had neurasthenia and was overdoing.

Patient is a tall, well-developed woman, some pigmentation of skin over cheeks and face. Long chest and abdomen. Face round and full. Patient is much depressed and weeps during the taking of the history. Knee-jerks very active; active dermatographia; pupils react to light and accommodation. Some tenderness in neck and along spine and over abdominal aorta.

REPORT OF CASES

CASE 1.—Miss E. L., aged 23, single, living at home, admitted to the St. Barnabas Hospital, Oct. 14, 1913, complaining of backache, insomnia, spells of depression, indigestion. Family history negative. Present history includes a long series of ailments of various sorts, curvature of spine at 5 years of age, at first thought to be tuberculous, later considered hysterical; chorea at 10 years of age; dysmenorrhea at 15 years of age; various abdominal operations finally terminating in hysterectomy in February, 1912. No cause given by the operating surgeon for the hysterectomy other than that he considered it best for the patient's general state of health. No pathologic lesions found.

History of present complaints dates back over a number of years and includes a long series of symptoms, including indigestion, vomiting, abdominal pain, pain in back, insomnia, constipation, attacks of mental depression with hysteric manifestations, crying spells, dizziness, aching in the neck, headache, eyeache and physical tire on exertion. Has had a slight nervous cough for years. Has dieted to such an extent that she can scarcely eat solid food of any kind. Patient is a tall, angular-looking girl, high cheek bones, long chest and abdomen, marked tremor upper eyelids, increased knee-jerks, pupils react to light and accommodation, no incoordination, some tremor of finger-tips, no enlarged thyroid, no exophthalmos. Patient presents the stigmata of a highly nervous girl; hands, arms and legs were constantly twitching during examination; seems melancholy and depressed. Careful physical examination of this patient, including searching examination of the lungs, revealed no evidence of organic disease. There was gastroptosis, a dilated kidney on right side, tenderness over abdominal aorta and along lower spine. Urine and gastric examinations negative, no occult blood in stools. Blood examinations showed slight secondary anemia (hemoglobin 87 per cent.). Wassermann reaction negative. Von Pirquet test positive. Patient was carefully observed in hospital over a period of two weeks. She had an occasional rise in temperature to 99.2. Pulse 85 to 100. She presented all the earmarks of a highly neurotic young woman, with frequent crying spells, much mental depression, vomiting attacks, headache, and slight dry cough. No sputum. Had two fainting spells while going to the bath room. Roentgen examination of spinal column and lungs negative.

On the fifteenth day after admission, patient was given 1/20 c.c. of Bureau tuberculin, showing a positive reaction (temperature 102) within sixteen hours after the injection. Following the positive tuberculin reaction the clinical diagnosis of neurasthenia was

3. Bureau tuberculin is the tuberculin made by the U. S. Bureau of Animal Industry. It is a 10 per cent. solution of Koch's old tuberculin. It is the tuberculin used in testing cattle for tuberculosis.

A careful physical examination was negative for organic disease. There was gastropnoxis. Urine and blood examinations were negative. No sputum. Pulse 95. Temperature showed an occasional afternoon rise to 99.2. A searching physical examination of the lungs was negative, except roughened breath-sounds in left apex. No impairment of percussion note. No râles heard. Von Pirquet test positive. No evidence of lues.

While under observation patient seemed a nervous, much depressed woman, cried at times and complained of aching pains in the head, neck, back, chest and limbs. On the fifth day a subcutaneous injection of 2 mg. of Koch's old tuberculin was given with a marked positive reaction (temperature 102.8) within sixteen hours following injection. No Roentgen examination of chest was made.

The diagnosis of neurasthenia was not confirmed. The diagnosis was made of tuberculosis (focus concealed) with chronic tuberculous toxemia exhibiting symptoms of so-called neurasthenia.

CASE 4.—Mrs. W. V., aged 23, married, housewife, one child, referred to the University Hospital June 2, 1913, complaining of headache, dizziness, indigestion, backache, irregular and painful menstruation, and tenderness in the lower abdomen; symptoms dating back two and one-half years. Family history negative. Previous history negative, except whooping-cough as a child.

The patient was carefully studied for sixty-three days in the surgical service of the hospital and then referred to the medical service with the diagnosis of neurasthenia. After her transfer the patient was again examined. She was a tall, rather poorly nourished woman, high cheek bones, long chest and abdomen, color slightly anemic, active dermatographia.

A careful thorough examination including urine, blood and Roentgen-ray chest study revealed no evidence of organic disease. Wassermann reaction negative. Von Pirquet test positive. The patient exhibited the earmarks of a highly neurotic woman, and the provisional diagnosis of neurasthenia was concurred in. Pulse 60 to 90. Temperature normal with an occasional rise to 99.4 in the afternoon.

On the twenty-fourth day after admission to the medical service patient was given $\frac{1}{20}$ c.c. of Bureau tuberculin with a typical positive reaction within twelve hours following the injection (temperature rising to 101.6).

The diagnosis of neurasthenia was abandoned. The presence of a positive tuberculin reaction justified the diagnosis of concealed tuberculosis, focus not determined; chronic tuberculous toxemia exhibiting the symptoms of so-called neurasthenia.

CASE 5.—Miss I. P., aged 24, Scandinavian, single, white, housekeeper, admitted to the University Hospital Oct. 26, 1913, complaining of shortness of breath, headaches, precordial pain, lassitude and weakness on physical and mental exertion.

Family history negative. Personal history negative except usual childhood diseases. The patient was treated five years ago for neurasthenia and took a rest cure in a hospital. Her present complaints date back three months and includes a history of mental and physical tire, some loss in weight, headaches, especially when she reads, poor appetite and indigestion.

Patient is a tall, fairly well-nourished girl, high cheek bones, long chest and abdomen, fair color, pupils react to light and accommodation, knee-jerks active.

A thorough clinical investigation of this case, including pelvic and rectal examinations, also urine, blood and gastric studies, was negative for organic disease. No sputum. Wassermann reaction negative. Von Pirquet test positive. Temperature normal with an occasional rise to 99.2. Pulse 70 to 96. Clinical diagnosis based on the history of physical and nervous exhaustion with negative physical findings was neurasthenia with astigmatism (Macnie).

On the thirty-first day after admission patient was given subcutaneously $\frac{1}{60}$ c.c. of Bureau tuberculin with a typical positive reaction (temperature rising to 101.4) within twenty hours after injection of tuberculin. The diagnosis of neurasthenia was then abandoned.

The history and the positive tuberculin reaction in the absence of evidence of other organic disease justified the diagnosis of concealed tuberculosis, focus not determined; chronic tuberculous toxemia exhibiting symptoms of so-called neurasthenia.

CASE 6.—Miss H. W., aged 21; single, white, stenographer, admitted to the University Hospital, Jan. 28, 1913, complaining of pains in abdomen, indigestion, dysmenorrhea and nervousness.

Family history negative except that mother died after five months' illness of probable tuberculosis of lungs. One sister now has chronic cough. Patient has never been strong, long history of backaches, menstrual troubles and recurring winter colds. In July, 1911, had a nervous breakdown followed by a period of weakness and prostration. Finally became so weak and run down that she had to stop work.

Present complaint dates back over two years and consists of a long history of ill-defined pains in upper and lower abdomen and left chest, associated with indigestion, eructations of gas, nausea, loss in weight, cold hands and feet, painful menstruation, prostration and weakness.

Patient is a fairly well-nourished young woman, seems weak and talks in a low voice; long chest and abdomen; color good; pupils react to light and accommodation; knee-jerks active; palpable postcervical lymph-glands.

A careful thorough physical examination of this patient, including repeated examination of the lungs, revealed no positive evidence of organic disease.

The apex of the right lung was questionable; there was marked visceroptosis; blood and urine negative; there was no sputum; von Pirquet test was positive; Wassermann test not made. Temperature normal. Pulse 70 to 100. No positive diagnosis could be made. The patient was high-strung and nervous and this fact together with the negative clinical findings led to the diagnosis of neurasthenia.

On the thirteenth day after admission patient was given $\frac{1}{20}$ c.c. of Bureau tuberculin subcutaneously with a typical positive reaction (temperature 100.4) within sixteen hours.

Roentgen examination of chest twelve days later showed "diffuse infiltration of both lung fields, especially marked in the right" (Bissell).

The diagnosis of neurasthenia was therefore abandoned and the diagnosis made of pulmonary tuberculosis with chronic tuberculous toxemia exhibiting symptoms of so-called neurasthenia.

CASE 7.—Miss M. L., aged 32, single, stenographer. Father died of tuberculosis of the lungs, four sisters and one brother dead of tuberculosis of the lungs. Never strong as a girl, subject to colds and bronchitis. Three years ago was in California for bronchitis one winter during which she gained 12 pounds in weight. Gives a long history of ups and downs with weakness, poor indigestion, exhaustion from physical effort, aching in the back and loss in weight.

Comes now for pains in her right chest and precordial region which she has had for about a week. Has had pains also in the left chest for a month or more. Pains are a dull ache, and chest is sore to pressure. Occasionally patient feels pains in axillae, left scapula and back. Deep breathing or cough does not aggravate them.

For about two years patient has had a clearing of her throat, more marked in the morning. Has lost 10 pounds in weight during the past year. Appetite is poor. Is bothered much with sleeplessness. Has pains at her menstruation, and now feels so weak and nervous that she has had to stop work.

Has been examined by many physicians and lung specialists, all of whom had suspected her of being tuberculous, but none of whom had been able to find evidence of tuberculosis in the lungs or elsewhere in the body and had, therefore, diagnosed her case as neurasthenia.

Patient is a fairly well-nourished girl, looks high-strung and neurotic, color pale, light hair and eyes, high cheek bones, long chest and abdomen, pupils react to light and accommodation, tremor of finger-tips, knee-jerks active.

A careful physical examination of this patient revealed no evidence of organic disease. A searching physical exami-

NEURASTHENIA AND TUBERCULOSIS—HEAD

1001

nation of the lungs was negative for tuberculosis. Patient had a moderate grade of gastropotosis. Sputum and urine examinations negative. Von Pirquet test positive. Blood-pressure 116. Pulse 90 to 100. Temperature normal.

Not being willing to accept the diagnosis of neurasthenia, and not being able to make the diagnosis of tuberculosis, the patient was subjected to an injection of $\frac{1}{2}$ c.c. of Bureau tuberculin, and gave a positive reaction (temperature of 102) within eight hours after injection was given.

The clinical diagnosis of tuberculosis (concealed) with chronic tuberculous toxemia exhibiting symptoms of so-called neurasthenia was then made.

CASE 8.—Miss L., aged 25, Jewess, single, stenographer. Family history negative except that mother died of tuberculosis when patient was a child at home.

Personal history negative except walking typhoid fever (?) five years ago. Operated on twice for pelvic displacements. Present history dates back six years and includes a long history of nervous symptoms, including headaches, backache, neckache, insomnia, cold hands and feet, indigestion, cough, exhaustion, rest cures, operations, treatment by osteopaths and Christian Scientists, etc. Insomnia and indigestion have been her most troublesome symptoms. Has been seen and examined by many physicians and the diagnosis of neurasthenia usually made. Has taken a number of rest cures from which she would temporarily improve and go back to work only to relapse into a weak, prostrated state, rendering her unfit for her occupation. Has lost 40 pounds in weight in the last six years.

Patient is an ambitious, intelligent, bright young woman, dark hair and eyes, high cheek bones, long chest and abdomen, slender limbs, pupils react promptly to light and accommodation, knee-jerks active, pulsating abdominal aorta, active dermatographia. Marked tremor of eyelids with eyes closed. No exophthalmos, no von Graefe's sign, no enlargement of thyroid.

A careful physical examination of this patient revealed no evidence of organic disease. There was marked gastropotosis and bilateral nephropotosis. Blood, urine and stomach examinations negative for organic disease. No Wassermann test made. Exploratory abdominal section negative for organic diseases in stomach, gall-bladder, appendix or elsewhere. Searching examination of lungs revealed no evidence of tuberculosis. Von Pirquet test negative. Temperature showed an occasional rise to 99. Pulse 80 to 100. The clinical diagnosis of neurasthenia seemed justified.

After patient had been under observation for six weeks and despite the negative von Pirquet, the patient was given $\frac{1}{2}$ c.c. of Bureau tuberculin with a typical positive reaction (temperature 101) within twenty-four hours following the injection.

The clinical diagnosis of neurasthenia was then abandoned and the diagnosis made of tuberculosis (focus concealed) with a chronic tuberculous toxemia exhibiting symptoms of so-called neurasthenia.

CASE 9.—Miss S. (referred by her physician as a case of neurasthenia and admitted to Asbury Methodist Hospital, Dec. 1, 1909), aged 23, living at home, family history negative except that two sisters have died of tuberculosis of the lungs. Has never been a strong girl. Has always been very nervous and of late on account of a mental worry has been bothered with a constant desire to take deep breaths. This deep breathing occurs during the day while she is awake; is not aware of it at night (is present while she is asleep). At times has a slight cough which has always been considered a nervous cough. No sputum coughed up. Has not lost in weight. Occasionally has slight fever (99.2). No sweats, no chills. For the last week has complained of feelings of distress in the upper abdomen. Patient is a fairly well-nourished girl, sensible and intelligent, seems high-strung and fidgety, good color, long chest and abdomen, pupils react to light, knee-jerks very active, tremor of eyelids. During the examination patient keeps taking long deep breaths in rapid succession, one after the other. The deep breathing is worse when she sits up than when lying down.

A careful physical examination of this case including a searching examination of the lungs reveals no evidence of organic disease. Blood, urine and gastric contents normal. Von Pirquet test positive. The abdominal aorta was pulsating and tender and there was ill-defined tenderness over the upper abdomen, but no mass. Patient was repeatedly examined but no conclusion could be arrived at.

On the seventh day after admission patient was given $\frac{1}{2}$ c.c. of Bureau tuberculin and gave a typical positive reaction with a temperature rise to 101.5 within fourteen hours following the injection. No Roentgen examination of the chest was made.

The diagnosis of neurasthenia was therefore not confirmed, but the diagnosis of concealed tuberculosis with chronic tuberculous toxemia producing neurasthenic symptoms was made. The focus could not be located.

CASE 10.—W. K., aged 29, male, single, American, carpenter, referred to the University Hospital, Feb. 16, 1912, as a case of nervous dyspepsia and neurasthenia. Family history negative. No tuberculosis. Denies venereal disease. Has had mumps and small-pox.

Dec. 7, 1911, patient began complaining of palpitation of the heart. Consulted a physician who examined his heart and pronounced it all right. The attacks continued for a number of days until his stomach was washed out, since which time the palpitation has not bothered him. Patient has not felt well since the attacks in December. Is bothered with belching of gas after meals, constipation, headaches, especially at night, has felt weak and nervous, has frequent urination, and at times ringing in his ears. Patient has no cough. He has lost about 17 pounds in weight since sickness came on.

Patient is a thin, spare man, fairly well-nourished, color good, answers questions promptly and to the point, is nervous and apprehensive about himself. Pupils equal, react to light and accommodation, knee-jerks active, slight cyanosis of lips and finger-tips, cervical glands just palpable.

A careful physical examination of this patient revealed no evidence of organic disease, except a questionable area on the upper right chest anteriorly below clavicle. Here the percussion note is slightly impaired, expiration somewhat prolonged and a few fine cracking râles could at times be heard at the close of inspiration close to the right sternal border in first interspace. Blood examination showed a secondary anemia of mild grade. Urine and sputum negative. Von Pirquet test positive. Gastric analysis negative except an increased acidity. Pulse 60 to 80. Temperature 97 to 98.4.

On the tenth day after admission patient was given $\frac{1}{2}$ c.c. of Bureau tuberculin with a positive typical reaction (temperature 102.0) within sixteen hours following the injection. Roentgen examination of chest March 1: "There is a rather marked thickening about the hilus of the right lung. A number of peribronchial lymph-nodes in both lungs. The right apex is distinctly more dense than the left." Roentgen diagnosis: Incipient tuberculosis (Bissell).

The diagnosis of neurasthenia could not be confirmed. The suspicious physical signs in the chest, the positive tuberculin reaction, the Roentgen chest findings justified the diagnosis of tuberculosis of the right lung with chronic tuberculous toxemia exhibiting symptoms of so-called neurasthenia.⁴

Donaldson Building.

ABSTRACT OF DISCUSSION

DR. NATHAN ROSEWATER, Cleveland: Dr. Head is right in distinguishing these cases of disguised starvation from neurasthenias. I believe a much larger class which have "that tired feeling" in the morning after sound sleep are obviously not neurasthenias, since the neurasthenic class after a night of rest with sleep wake up refreshed from the rest of nerves, brain and body, and only as they tire out sooner or later do they fag. Another class described in the paper which I read before this Section in 1908 as cases of "disguised starvation" should also be excluded.

These are cases of more or less undernourishment resulting in more or less bankruptcy of brain, muscles, organs or tissues with impoverishment of circulatory fluids, which condition is perhaps the greatest cause of non-resistance to tuberculosis or other germ invasion, because neither the blood-stream nor the exhausted cells are in any condition to offer the necessary 100 per cent. or more of resistance to the invading germs from without, nor are they able to prevent the breaking down of foci already present. A class akin, is of those who wake refreshed but complain of wearing out before or soon after noon, unable to keep brain and body at work. On questioning these we find that they have taken for breakfast a cup of coffee, with or without a little bread. This insignificant meal cannot prevent the human machine from breaking down, any more than an automobile can be kept going when one starts away with a pint of gasoline instead of five gallons. These patients when advised to eat three or four eggs for breakfast come back reporting that they are veritable indefatigable steam-engines. Tuberculin may give a positive reaction in nearly all cases in adults but that does not prove active tuberculosis. A woman patient suffered from insomnia, but was otherwise well. Roentgenograms were made and she was told she had pulmonary tuberculosis, basing it on the Roentgen-ray findings and rapid pulse. She had neither fever, cough, râles nor other symptoms. She was examined by three able men than myself and no active tuberculosis found. This was nearly five years ago and she is still in excellent health. As to the enteroptoses, they may be primary or secondary, mostly the latter. I have seen many with nephroptosis, gastroptosis, etc., some with Stiller's habitus and quite a number without. These ptoses are due to asthenias, occurring before or after the development of the habitus, and caused primarily by a large variety of undermining, exhausting influences, metabolic, toxic, infectious, psychic, or by overstrain or underfeeding, and not until the primary causes and the ptoses are overcome will these secondary asthenias respond to treatment.

DR. F. M. POTTENGER, Los Angeles: Dr. Head has illustrated the important fact that neurasthenia has a tuberculous toxemia as an underlying cause in a large percentage of cases. Tuberculosis affects all of the systems of the body, and, strange to say, even the symptoms of the early pulmonary form of the disease calls the attention away from the lungs rather than to them, the larynx, the heart, the stomach and the nervous system seemingly being affected. This neurasthenia is better understood when we recall that tuberculosis begins in childhood; that nearly every individual is affected; that the lesion heals in some at once, but in many passes through stages of quiescence and activity, extending now and then from the primary focus of infection to other parts of the body, so that necropsies in adults show more than 50 per cent. in and about the apices of the lungs. From such lesions as fail to heal, toxins are given off which have a profound effect on the nervous system, producing neurasthenia. Many young people who fail to develop properly, who have lowered resistance and manifest an unstable nervous system belong to this group. Such patients often respond remarkably well to the measures used in the treatment of tuberculosis and are definitely benefited by tuberculin treatment. Many believe that the phthisical habitus is often a result of tuberculosis instead of a cause. Unless the medical profession can get away from their conception that tuberculosis is the disease which we usually term consumption, and will recognize the early infection and the slight symptoms which are produced months, sometimes years before the active advanced stage manifests itself, it will miss completely the point of the modern teaching concerning this disease.

DR. CHARLES STOVER, Amsterdam, N. Y.: Myasthenia gravis should be differentiated before determining that the patient is suffering from neurasthenia. It is not uncommon, particularly among those who are interested in diseases of the nervous system, to meet both the neurasthenic and tubercu-

lous type of cases which, in course of time, come under the classification of myasthenia gravis.

DR. ELIZA MOSHER, Brooklyn: I have been much interested in the statement that nearly all of the patients included in Dr. Head's report had enteroptosis. According to Sir Arbuthnot Lane of London, intestinal stasis due to enteroptosis is one of the underlying causes of a large number of special diseases, tuberculosis among the number, and I believe he is right. We are finding behind many cases of neurasthenia, melancholia and even epilepsy, the systemic poisoning produced by the products of chronic intestinal stasis, and as we become skilled in the diagnosis of gastro-intestinal displacements, "bands" and "kinks," we shall more and more often find one or all of these conditions present in the abdomen of patients suffering in these and other ways. I also understood Dr. Head to say that in the cases he reported the long slender trunk so common among young tuberculous patients was a common feature. I have yet to find a delicately built girl of this type, especially if she has broad hips, who does not manifest a strong tendency to enteroptosis. Dr. Head's cases should arouse us all to the importance of making a careful examination of the abdomen in all of our patients and especially in slender-bodied undernourished, neurasthenic girls and women.

DR. A. J. CAFFREY, Milwaukee, Wis.: We all know that a very large number of neurasthenics pass through the free dispensaries, and I have charge of the medical department of the free clinics in the Marquette University at Milwaukee and have been making routine tuberculin tests of the patients we class as having neurasthenia. In nearly all cases, perhaps 90 per cent., there is a positive reaction to subcutaneous injections of tuberculin and also to the von Pirquet test. I think, from these observations, that there must be some direct connection between neurasthenia and concealed tuberculosis.

DR. JOHN RITTER, Chicago: I have observed that in at least 40 per cent. of the so-called neurasthenic patients, tuberculosis in some form is present. It, like walking typhoid, belongs to that large category of diseases in which more than 50 per cent. of patients are tuberculous. We see it in cases of hypo-acidity, of which at least 30 per cent. point to tuberculosis. All these, like tuberculosis following trauma, are manifestations of a previous existence of tuberculosis, the symptom-complex only following in the train of a previous disease. Tuberculosis is, as Dr. Pottenger points out, like syphilis and follows a similar course. The full picture of pulmonary tuberculosis is only the last or tertiary stage of the disease following long after the primary infection. I cannot too strongly emphasize that, in the use of tuberculin for diagnostic purposes, the intracutaneous mode of application should be used and not the subcutaneous. In the public schools in Vienna every child, at entrance, is given a von Pirquet test for diagnostic purposes. To all who do not react to this test a second one is given intracutaneously, and it has been observed that about 80 per cent. of those children who do not react primarily to the von Pirquet react positively to the Mantoux test. With regard to the cases of healed lesions, the application of tuberculin for testing purposes is of no value because from the very nature of the disease we know that these cases all react positively.

DR. TOM A. WILLIAMS, Washington, D. C.: I cannot agree with Dr. Head's statement that all neurasthenia is due to latent tuberculosis. While I am one of the few neurologists who believe that neurasthenia, unlike psychasthenia and hysteria (which are psychogenetic), is a purely physical disorder and, moreover, due to some cause or other extraneous to the nervous system, rather than to hypothetical "nerve fatigue," I cannot accept latent tuberculosis as the sole source. We must remember that symptoms quite similar to those described by Dr. Head, are not uncommon, as every southern physician knows, in the early stages of pellagra, in hookworm disease and in latent malaria. Besides dys-thyroidea as well as other glandular irregularities is responsible for disorders often labeled neurasthenic. In connection with Dr. Head's thesis, however, it is interesting to

recall the investigation made in the neurologic clinic of the New York Postgraduate Hospital some years ago by Dr. Haskell, who found many of the neurasthenics suffering from a tuberculosis which had been overlooked by other physicians. Many of us regard enteroptosis not as the cause but as the effect of asthenic states, to which also the intestinal disorders may be secondary; furthermore, it must be remembered that many cases of enteroptosis develop neither neurasthenia nor tuberculosis. With these qualifications, Dr. Head's paper should be of the greatest value in warning practitioners against permitting themselves to make a diagnosis of neurasthenia.

DR. WALTER B. SWIFT, Boston: I agree with Dr. Williams that not all patients with neurasthenia have tuberculosis. A young woman in the neurologic service of the Boston City Hospital presented all the typical signs of neurasthenia. Six or eight months after that diagnosis was made she died of carcinoma of the stomach. Neurasthenia is not a useless word. It makes a good waste-basket—something to say in place of "I don't know." We would do better to dispense with not the word but the waste-basket and instead give these patients further exhaustive physical and mental investigation.

DR. ALBERT ROBIN, Wilmington, Del.: Neurasthenia is a word rather loosely used to the great disadvantage of the suffering public. This term "neurasthenia" is now used as the term "malaria" was formerly used. The more we practice medicine the better diagnoses are made and we do not have to fall back on these terms of doubtful significance. In connection with my work at the tuberculosis clinic for the past ten years fully 20 per cent. of those applying for treatment have no other physical examination made except a casual one through the patient's clothing. I believe that neurasthenia is intimately associated with the early stages of tuberculosis, and because few men are able to make a diagnosis of incipient tuberculosis it is necessary to formulate some scheme by which a diagnosis in the early stages of tuberculosis may be arrived at. The busy doctor has not the time to make a thorough examination in these cases; in fact he hardly has the time to read his medical journals, and thus familiarize himself with latest methods. It should be remembered, in making a differential diagnosis between neurasthenia and tuberculosis, that in the former disease there is no elevation of temperature. In every case of tuberculosis or tuberculous toxemia, in these cases of concealed tuberculosis at one time or another there is a slight elevation of temperature. This temperature curve appears particularly after exercise. The question of exercise in making a diagnosis of concealed tuberculosis is one of great importance, and if patients are kept under observation for any length of time the diagnosis can be readily made. I am referring to slight exercises. I generally instruct the patient to walk to my office every evening, for a week, and I take his temperature immediately on arrival. A slight elevation of temperature will appear which will not appear at other times. I am in favor of an educational campaign among physicians that will cause them to be more careful in examining their patients in order to detect concealed tuberculosis or the disease in its earlier stages. I want particularly to emphasize the importance of detecting this elevation of temperature following exercise, which is as diagnostic as the reaction following injections of tuberculin, and far safer. The symptom-complex of neurasthenia plus slight elevation of temperature on exertion, plus rapid pulse, means tuberculosis.

DR. J. P. MUNROE, Charlotte, N. C.: In a paper which was read at the state society of North Carolina it was stated that the tubercle bacilli found in animals in the mountains were acid-stained and in every animal examined they were practically identical with the tubercle bacilli found in the human body. Also the symptoms appearing in these tuberculous animals were like those that appeared in the human being.

DR. ROBERT N. WILLSON, Philadelphia: It would seem as though one were taking a rather radical step in endeavoring to include in the term "tuberculosis" all or even a large

percentage of the cases of neurasthenia or nerve-tire. No one questions that the tuberculous toxin may and does predispose to neurasthenia in certain cases. Just as certainly there are many patients with neurasthenia who show no evidence during life of tuberculous infection, either before or after their cure. Most cured neurasthenics enter on their convalescence without any treatment directed toward or suitable to tuberculosis. Again, many cases of neurasthenia have a definite etiology that can be traced altogether distinct from tuberculosis, such as cardiac disease, intestinal toxemia, nervous overwork or worry, syphilis, oftentimes the very lack of a definite object in life and the consequent irritation and fretting of unsympathetic home surroundings. Neurologists speak of various types, sexual, cerebral, cerebrospinal, gastric and circulatory. Often these terms are more closely related to the etiology than to the symptomatology. Not one of the pictures is necessarily tuberculous. Of course any one may be, in a given instance. An important etiologic phase of the subject has been altogether neglected in the discussion, which would have been touched on at once had there been a thoroughgoing neurologist present. No one has mentioned the fact that practically every case of neurasthenia develops from neurotic and often from positively neurasthenic soil. We seldom fail to find the parentage of a neurasthenic tainted on one side or the other with nervous invalidism. Alcoholism, epilepsy, insanity, hysteria and neurasthenia are the progenitors of neurasthenia in the second generation. Tuberculosis may or may not be present as a concomitant, and perhaps as an exciting factor. When the soil is tainted, however, tuberculosis is not needed as a factor in the causation of the neurasthenia, which will develop in the child of the neurotic parent when the conditions are right.

DR. GEORGE DOUGLAS HEAD, Minneapolis: My contention is not that all cases of so-called neurasthenia harbor a latent tuberculosis, but that in the group of cases clinically diagnosed as neurasthenia, after excluding syphilis, heart-disease, exophthalmic goiter, gastric ulcer, nephritis and all other known organic diseases, a certain number remain in which no organic lesion can be found. This "remnant group" has been considered negative for organic disease, and because of the existence of these cases the clinical entity neurasthenia has been kept alive. Now when the individuals in this group supposed to be free of organic disease are tested with tuberculin, a large percentage of them show evidence of harboring an active tuberculous lesion, so concealed, however, as to escape detection by the usual clinical examination even of the most searching kind. I contend that the symptoms of nervous and physical exhaustion displayed by these patients and now diagnosed as so-called neurasthenia is in reality a clinical expression of a concealed tuberculous lesion and that we should recognize a new clinical symptom-type for concealed tuberculosis which is the symptom-type we now give to neurasthenia. The question has been asked, What percentage of the cases in this "remnant group" of so-called neurasthenias give evidence of harboring concealed tuberculous lesions? I am not prepared to answer this question at this time because my series of observed cases is not large enough to give reliable data. Roughly speaking, I should say that about 20 per cent. of the "remnant group" fail to give a reaction to a subcutaneous injection of tuberculin.

The Thyroid Problem.—How the tissues are affected by the secretion of the thyroid is an enigma. But the fact is certain. For the adrenal cortex even so much as that cannot be said. There is only the conjecture that this fatty substance is essential to a man's strength and manhood. . . . To the Australian or "black fellow doctors" the fat above the kidney was magic. If by incantations it could be removed from an enemy as he slept, the victim would surely lose his strength and die. We know as much, that there is no warm-blooded life without these glands.—T. R. Elliott, *Brit. Med. Jour.*, June 27, 1914.

INTRARECTAL ADMINISTRATION OF SODIUM SALICYLATE IN ACUTE RHEUMATIC FEVER WITH SATISFACTORY RESULTS*

LOUIS G. HEYN, A.B., M.D.

Junior Physician to the Cincinnati General Hospital

CINCINNATI

In 1912, I published a report¹ covering 22 cases in which the intrarectal administration of sodium salicylate in acute rheumatic fever was apparently successful. The present report is based on 100 additional cases in hospital and private practice, the results of which indicate the advantage of this method over the usual modes of treatment in acute rheumatic fever and I would urge the adoption of the method at the hands of this representative body.

The intrarectal method of salicylate administration was adopted in 1911 on the East Medical Service in the Cincinnati General Hospital after observing the number of refractory cases of acute and subacute rheumatism in the wards. Previous to this, text-books had mentioned the possibility of such a method of treatment, while very meager reports had appeared in the literature (notably, however, Erlanger's in 1893 from the Klinik Von Ziemsens), but no attempt had been made to urge the general adoption of this measure as the method of choice. Erlanger² reported twenty-five cases with seventy-eight salicylate enemas and his report showed very satisfactory results with as small a dosage as from 6 to 8 gm. daily, and also gave satisfactory proof of the ready absorbability of the drug by the rectum.

But the value of the intrarectal sodium salicylate administration has not met any general recognition. Many other drugs have been given per rectum, most often for their local effect, as quassia, silver preparations, tannic acid, while certain others, as opium, digitalis, collargol, quinin and various serums have been used for their remote effects, but most of these latter if not to be administered by mouth may be used preferably by the subcutaneous method, a method not to be so readily adopted for salicylate medication, though Seibert reports satisfactory results. Heretofore we have permitted ourselves to be satisfied with the administration of sodium salicylate by mouth and the results have without doubt justified the designation of the drug as a specific in acute rheumatic fever.

The salicylic acid group of substances is bactericidal and according to Meyer and Gottlieb, salicylic acid is probably etiotropic, that is, acting on the cause of the disease. If the recent investigations of Pointon and Paine and Rosenow are to be regarded as conclusive, we must look to a bactericidal agent for rational therapy and in the absence of a specific serum or vaccine, sodium salicylate and certain newer salicylic acid preparations as, salol, aspirin, salipyrin remain our principal weapons in acute rheumatic fevers.

But why should there be so many failures with salicylic acid therapy, which is in every way to be regarded as a specific? No doubt in many instances there are foci of reinfection, in which surgical meas-

ures may be necessary. But in very many instances there has been insufficient dosage due most often perhaps to the frequent intolerance of the drug by mouth; and following on this failure the drug manufacturers have not been slow to introduce preparations more readily tolerated, but without doubt less efficient than sodium salicylate in the therapy of acute rheumatic fever. There is still much indifference among medical men toward pharmacology and therapeutics, perhaps inherited from the days of therapeutic nihilism, and if we fail in a therapy learned possibly in student days, many are apt to seek at once the new therapeutics as taught by the detail men.

If a routine administration of sodium salicylate has not always given brilliant results as it often does, however, the drug should not have yielded its position so largely to the newer salicylic acid preparations. As a solution to the problem of rheumatic therapy, intrarectal administration of sodium salicylates is offered as the method of choice and as excellent a therapist as the late Dr. Frederick Forchheimer declared it to be the best method yet devised for the treatment of acute rheumatic fever.

The method has for its justification its ability to answer the requirements of any therapeutic agent: (1) the ease of administration; (2) the ready absorption of the drug; (3) a minimum of untoward effects; (4) the ability to administer large quantities of the preparation as is to be advocated in bactericidal therapy; (5) the removal of the residue of the drug from the bowel by subsequent enema, if the dosage ever proves excessive; (6) the results are more prompt than by any other measure.

EASE OF ADMINISTRATION

I have used intrarectal salicylate therapy in 125 cases of joint affections, the majority of which occurred in hospital practice, where, to be sure, the method is most easily carried out. The method, however, lends itself readily to private practice as well. Recently in a severe protracted case of rheumatic fever occurring in a rural district, I advised the removal of the patient to a hospital in Cincinnati, in order to carry out the rectal therapy. The wife of the patient thought that she might be able to carry out the treatment at home and she did so and was promptly successful. I received a similar report from a physician in South Dakota recently and there is reason to believe that the method has been widely used since my report two years ago.

The method of administration is as follows: A cleansing soapsuds enema is given and as soon as effective is followed by the salicylate enema given by means of a Davidson syringe and a rectal tube inserted 6 to 8 inches. The dose varies according to the size and sex of the patient and also according to the severity of the case. The first adult dose in men is usually from 8 to 10 gm., in women 6 gm., women being apparently more susceptible to salicylism than men. The synthetic salicylate has been used, especially since the clinical research carried out by the Council on Pharmacy and Chemistry, in which I had the privilege of assisting, the results of which proved the practical similarity in action of the synthetic and natural salicylates. The amount of salicylate to be given is incorporated in 120 to 180 c.c. of plain or starch water with the addition of 1 to 1.5 gm. of opium tincture. The dose of salicylate may be repeated in twelve hours, when it can usually be determined whether symptoms of salicylism will appear. Usually, however, a daily

2. Erlanger: *Deutsch. Arch. f. klin. Med.*, 1893, li-iii.

enema suffices with doses increasing perhaps from 30 to 50 per cent. daily until the limit of tolerance is reached. The largest daily dose which has been given has been 24 gm., and the only symptoms of salicylism which usually have appeared have been tinnitus and excessive perspiration. Once or twice there has been vomiting present, which might occur in the administration of even a simple enema. Where salicylism has been excessive, it usually appears within from three to six hours and the remaining unabsorbed portion of salicylate may be washed out of the bowel by subsequently indeed, and it is rare also that the rectum is intolerant of the drug. I do not agree with Erlanger that the plain water enema is more readily retained than the starch water, although the former is more simple, which is in its favor. It might be said at this point also that salicylate medication must continue some days after all symptoms have subsided, otherwise recurrences are frequent.

READY ABSORPTION

In testing out the value of this method it was interesting to note the promptness of absorption by the rectal mucous membrane. Usually within fifteen minutes, always within thirty minutes, a strong ferric chlorid reaction appeared in the urine and the reaction usually persisted for from forty-eight to seventy-two hours after the administration of the drug ceased. To show also that complete absorption was usually possible, the stool subsequent to the salicylate enema was examined by acidifying with hydrochloric acid, extraction with ether and testing with ferric chlorid. As a rule usually within from twenty-four to thirty-six hours, depending on the size of the dose, there was complete absorption as shown by a negative reaction. (It would seem that the greatest absorption is within twelve hours.)

PROMPTNESS OF ACTION

Results show promptness of action. If we consider acute rheumatic fever as a disease which runs a most variable course, with a migrating involvement of usually many joints, each affected joint remaining at an acute stage of inflammation for several days, the attack possibly running a severe course of one or two months, often in spite of a more or less vigorous treatment (or there may be a less severe course involving fewer joints or perhaps only a subacute recurrent course of the disease) it may be readily seen that a satisfactory judgment of a therapeutic measure in this disease may be very difficult. A satisfactory therapeutic agent in acute rheumatic fever, however, should accomplish the following results: promptly lessen and eventually abolish all symptoms of the disease, materially shorten the course of the disease, reduce cardiac complications to a minimum and possibly prevent recurrences.

The following illustrative cases in which the intrarectal administration of sodium salicylate has been resorted to may be convincing.

CASE 1.—Man, aged 32. Attack began ten days previous to admission to the Cincinnati Hospital, with successive involvement of the right hip and right knee, left knee and ankle and left shoulder. On admission the joints most acutely affected were the left elbow, left shoulder, left wrist and several phalangeal joints of both hands. The temperature reached 102 F. the first day. A salicylate enema of 10 gm. was given and a similar enema twelve hours later with complete cessation of symptoms and prompt drop of the tem-

perature to normal. Three subsequent enemas of 10 gm. each were administered on three successive days with no recurrence or cardiac complications, the patient insisting on leaving the hospital four days after admission.

CASE 2.—Man, aged 34. On admission to the Cincinnati Hospital patient had a temperature of 103 F. and involvement of both knees and both ankles acutely. Ten gm. of sodium salicylate were given daily per rectum. The second day of residence in the hospital the temperature reached 102.4 F. and only the right knee remained acutely inflamed. The third day the temperature had reached normal and there were no joint symptoms remaining. The patient insisted on leaving the house on the fourth day.

CASE 3.—Colored woman, aged 27. Patient had involvement of both ankles and wrists and a temperature ranging from 101 to 102 during three days' residence in the hospital, during which time sodium salicylate (20 grains) was administered by mouth every three hours during the day. Symptoms were uninfluenced by medication per os. After a single salicylate enema of 10 gm. the temperature dropped to normal and remained there and there was a complete subsidence of symptoms. The enemas were continued for four days subsequently.

CASE 4.—Man, aged 39. Admitted July 16, 1912, with a temperature of 101.6 F., pulse 108. There was involvement of both knees and ankles and both shoulders and wrists. Sodium salicylate enemas of 10 gm. were given daily. Three days later there was a maximum temperature of 100 with maximum pulse 104 and all joints except wrists were improved. The fourth day 13.3 gm. of sodium salicylate were given with complete cessation of symptoms, but with some salicylism and the enemas were discontinued. On the fourth day after discontinuance of the enemas, however, there was some recurrence of joint symptoms and 13.3 gm. were administered for four successive days in spite of some tinnitus and excessive perspiration. The temperature became normal and the joint symptoms subsided completely within ten days, during which time a total of 100 gm. of sodium salicylate had been administered. This case was somewhat refractory on account of the salicylism, but we were able to carry the treatment carefully to a successful issue.

These cases are fairly illustrative of the efficacy of the intrarectal salicylate therapy and if the more common methods of treatment in acute rheumatic fever have so often been disappointing, the intrarectal method is offered as a very safe and reliable solution to the therapy of this serious affection.

22 West Seventh Street.

ABSTRACT OF DISCUSSION

DR. E. W. MITCHELL, Cincinnati: I wish to corroborate the report made by my associate concerning the value of the rectal method of administering the salicylate. To obtain the specific action of the drug, the primary doses should be large. It is often quite difficult to give sufficiently large doses by the mouth. We have seldom found difficulty in giving by rectum from 75 to 150 grains, twice daily. That the drug is promptly absorbed is shown by its early appearance in the urine, as Dr. Heyn stated, and also by the relief of pain, reduction of temperature, etc. Notwithstanding these evidences of absorption, we have found almost constantly that the ringing in the ears, nausea and other unpleasant effects are much less marked than when given by the mouth. Why this should be so I do not know, unless the local irritation of the stomach is responsible for many of the unpleasant effects of the salicylate. We believe that salicylic acid is a specific, but that it must be given in large doses in the early stage of the disease. It has been objected that while salicylic acid itself is a germicide, its salts are very feebly so, and however given salicylic acid always circulates in the blood as a salicylate. Dr. Wood has recently offered an ingenious explanation in answer to this objection. His theory is that the excess of carbonic acid in the congested areas converts the salicylates into salicylic acid, enabling it to exert its germi-

cidal or antiseptic power. I have also found the rectal method successful in private practice, whenever a competent nurse was in charge.

DR. JOSEPH L. MILLER, Chicago: Dr. Heyn shows that salicylates when administered by rectum are actually absorbed, but it is difficult to understand why salicylates by rectum in a certain dose should have a greater action than the same amount by way of the mouth, as, after all, it is apparently a question of the amount of the drug absorbed and we know that salicylates are readily absorbed by the gastro-intestinal tract. I believe one explanation of the excellent results Dr. Heyn obtained was the fact that the doses he employed were relatively large, larger in fact than the ordinary dose administered by mouth, and if the absorption was complete by the rectum it would have the same effect as if the equivalent amount were given by mouth. His work shows that in those cases in which the drug is not tolerated by mouth, it can be well taken by way of the rectum. I differ somewhat from Dr. Heyn, that salicylates are a specific in rheumatism, as statistics show that patients treated by salicylates remain in the hospital quite as long as those receiving other forms of treatment for their arthritis.

DR. J. N. UPSHUR, Richmond, Va.: In the discussion of this subject a few years ago in this Section, a number of speakers stated that their practice was to give large doses of salicylates, often as much as 300 grains in twenty-four hours, that endocarditis was a troublesome sequel, and they were at a loss to explain why. I said then practically what I repeat now. In the treatment of rheumatism, a good dose of a mercurial should be given at the start. The pronounced acidity of the sweat and urine is a conspicuous symptom, indicating the administration of alkalis until these excretions are neutral. My practice is to give, well diluted in water, potassium bicarbonate, 10 grains every two hours for forty-eight hours, following it with small doses (5 grains) of sodium salicylate every two hours for about two days. Relief is usually prompt. I never give more than a dram of salicylate in twenty-four hours, and rarely that much. I believe that large doses of salicylates predispose to the development of endocarditis, and the patient is much more liable to relapse, than if a foundation is laid by the exhibition of the mercurial, followed by the alkali. I desire to enter my protest against these excessive doses of the salicylates as being most harmful and dangerous.

DR. J. M. RECTOR, Columbus, Ohio: I have used this method successfully by a more satisfactory and thorough method. The solution is introduced into the colon with a large rectal tube to the point of toleration; the irrigator is then disconnected from the rectal tube and the solution forced into the upper parts of the colon by introducing air behind the solution with the aid of the Politzer bulb; the Politzer bulb is then removed and the solution which was not carried out of the sigmoid permitted to flow out of the tube. More solution is then introduced and the Politzer bulb again used until the entire colon is moderately distended. This traps the solution and carries it higher with a more equal distribution along the tract, increasing the surface through which the drug may be absorbed. This procedure is painless and I have been able to get better results with smaller doses in greater dilution, and this method also assists in elimination and drainage of the entire alimentary canal and leaves the upper part of the tract undisturbed so that it may follow its normal digestive activities uninterrupted. The three advantages are: 1. It increases the resistance of the patient by not disturbing the digestive ability in the upper part of the alimentary canal. 2. It increases the elimination and relieves all tendency to absorption from a constipated colon. 3. It gives the direct introduction of salicylate of soda in large doses with all its beneficial effects and without the digestive disturbances which usually follow the use of this drug by mouth.

DR. JAMES TYSON, Philadelphia: In 1896 my attention was called to the efficiency of this mode of administration of the salicylates advised with a view to getting rid of the unpleasant gastric symptoms so often associated with the use of salicylates by mouth. Of late years, however, it has

been found possible to refine the salicylates so as to get their effects without the disagreeable nausea. Aspirin, for instance, is a result of such refinement, does not disturb the stomach nearly so much and is equally efficient, rendering administrations by the rectum less essential.

DR. NATHAN ROSEWATER, Cleveland: When salicylates first began to be used in the New York Hospital, in 1878, I saw enormous doses given with remarkably good results compared to the older methods. Germ life, metabolic and other causes have been studied since then. Knowing that salicylic acid is a powerful inhibitor of fermentation, 1 grain being sufficient to preserve a pint of fruit-juice or other saccharine fluid, it occurred to me years ago that in proportion to the body-fluid such doses were entirely out of proportion, and the unnecessary and perhaps harmful effects far in excess of that required to inhibit germ life. I began at first to give 10 grains in chronic lithemic cases, before meals, when the stomach was practically empty—at least then the salicylate would not inhibit the action of the proteolytic and carbohydrate enzymes—and in acute cases and later in all cases to give only 15 to 20 grains at bedtime, three or more hours after supper. During the day I depended first on alkaline laxatives, such as citrates and tartrates to empty the gastro-intestinal canal, and on sodium iodid and other haloid salts to reduce the viscosity of the blood-stream and to relieve the heart of overtension, sparing it and aiming to avoid damage to this readily damaged organ. By elevating the lower extremities and even the upper ones, using gravitation to assist the venous return and sparing the cardiac mechanism, my results have been most satisfactory. For instance, in a very stout woman, aged 67, with all the joints of the lower extremities red, swollen, and very painful, temperature 102 F. and the digital extremities also swollen, I succeeded in having her on her feet in twelve days, without relapse. I have not given atophan, although my colleagues have been instructed to use it whenever salicylates should fail. The same is true of other preparations which I have kept on hand but have had no use for, although I use and have prescribed annually for many years, with this small dosage, approximately 100 pounds of sodium salicylate, not the natural, but the ordinary synthetic quality. I am glad to see that Hanzlik at Lakeside Hospital has corroborated the fact that the so-called natural salicylic acid has no advantages over the U. S. P. synthetic product. I have never seen ill effects except rarely when the stomach was not empty, the hydrochloric acid still present, liberating sufficient salicylic acid to irritate the gastric mucosa into distress or even to cause vomiting.

DR. W. W. TOMPKINS, Charleston, W. Va.: Our duty in this class of cases does not consist in how few days our patients are in the hospital, or confined in their homes, but our chief object should be that, when our patients get out, they should be free from endocarditis and its unpleasant symptoms. The question each physician should ask himself is how efficient is the patient after an attack of acute rheumatism? The method and dose of administration of a medicine is but secondary. Few of us have such large experience as Dr. Miller when he treats 2,000 cases by one method and 1,600 by another. Each of us has an experience, it may be relatively small; but what is important is the percentage of actual recoveries. When cases respond so readily to remedies as reported by Dr. Heyn may it not be that we would in such cases take a too optimistic view and not safeguard our patients for a few days or weeks by rest and freedom from work or exercise? Is it a safe practice to permit a patient four or five days after his initial symptoms to leave his bed or the hospital and go about or resume his vocation? If the joints of the lower limbs are involved we get a forced rest because it is painful and impractical to get about, but if a wrist or elbow is involved our patients can go about and will do so if we do not restrain them or admonish them as to their danger. The reduction of fever and the allaying of pain should be aimed at, but the important point to keep in mind is the specter of a diseased heart with all its unpleasant sequels. Dr. Heyn mentions treating 124 cases by this method—quite a large number. Will

VACCINES IN PERTUSSIS—HESS

1007

THE USE OF A SERIES OF VACCINES IN THE PROPHYLAXIS AND TREAT- MENT OF AN EPIDEMIC OF PERTUSSIS*

ALFRED F. HESS, M.D.
NEW YORK

Last December pertussis broke out in the main building of the Hebrew Infant Asylum, an institution which houses about 375 children, ranging in age from a few days to 6 years. It soon became evident that the disease was destined to assume considerable proportions, and that we were on the threshold of an epidemic. An occurrence of this nature offered an exceptional opportunity to make an extended test of the value of vaccination in this disease.

The study of an epidemic within the confines of an institution has marked advantages over the study of an equal number of cases selected from hospital or private practice. In the first place, it must be evident that the fact that an epidemic originates from a single source, that the cases are due, in all probability, to infection with the same type of micro-organism, greatly simplifies the solution of the problem; it negatives the question of whether a difference in the severity of symptoms is due to a variation in virulence of the invading bacteria. In hospital or in private practice, on the other hand, the cases must always have originated from manifold sources. It is probably also of advantage, from the standpoint of comparison, that these institutional children belong to the same stratum of society, that they have for the most part been reared for a considerable period within the same walls, having the same daily routine, including similar food and an equal amount of outdoor life. These are some of the conditions which are insisted on in considering the course of experimental infection among laboratory animals, but which can rarely be controlled in a study of infection in man.

Many of the hospital studies of the treatment of pertussis are, however, open to the severer criticism, that owing to the poorly defined onset of this disease there is no means of knowing how long the children were ill in their homes. This fact is naturally of great importance in considering the success of treatment. All these objections can likewise be raised in regard to cases treated in the dispensary or in ambulatory practice; in addition, this type of case is open to the criticism that one must rely solely on the opinion of ignorant parents in judging the efficacy of the treatment.

PROPHYLACTIC USE OF VACCINE

We shall first consider pertussis vaccine in its prophylactic use. Here a field of exceptional promise presented itself. Two hundred and forty-four patients were inoculated with four different vaccines. Vaccine 1 consisted of a typical strain of the Bordet-Gengou bacillus obtained from Parke, Davis & Co., and two atypical strains. Vaccine 2 was "Bacterin" (Parke, Davis & Co.), which is stated to be composed of a pure culture of the bacillus of pertussis. Vaccine 3 was prepared from four typical cultures of the Bordet-Gengou bacillus isolated by Dr. Anna Williams of this laboratory. Vaccine 5 may be termed an autog-

he please state how much lower his percentage of endocarditis is than we have by the method of administering the salicylates by the mouth. It is to the hospital clinician that we look for our statistics in these matters.

Dr. Louis G. Heyn, Cincinnati: I desired to state in the paper the results, in general, of the therapy and to cite a few instances fairly illustrative of the response of a class of cases to a definite line of therapy. The proof of the methods suggested must rest on the observations of those who are quite impartial in their judgment of results obtained. Dr. Miller's discussion was enlightening to me. It may be that what he said is a strong argument against the bactericidal effect of the salicylates, for he injected various bacteria and then gave the salicylates with apparently no effect on the bacteria, which would tend to prove that the salicylates have no bactericidal effect. Salicylates have apparently never had any effect where there is evidence of a general bacteremia as would be indicated by an endocarditis, and animal experimentation and clinical results are not always in accordance. The more I see of cases of acute rheumatic fever and the promptness with which this affection reacts to the salicylates the more I am inclined to believe that the drug must have some direct effect on the bacteria in this affection. I am quite in accord with the alkaline therapy with its frequently good results; it is also well known that many patients recover without any therapy, but there are few diseases causing such severe suffering as acute rheumatism, and most of us will at least seek the analgesic action of the salicylates. I must again answer the contention for the drug by mouth. Large doses by the mouth are possible and effectual in many cases, say from 20 to 30 grains five times a day, but this amount cannot be continued many days. The attack may be subdued within ten or twelve days; but not always, as Dr. Rosewater contends. On the other hand, one sees many cases prolonged weeks or months even in spite of the salicylate treatment. Someone has said that the salicylates predispose to cardiac affections. I have given it even in cases of marked cardiac arrhythmia and have seen no untoward effects, so far as I could judge. Dr. Rector's suggestion that this method of administering the enema be modified by the use of the Politzer bag, instead of the Davidson syringe in our method, would seem feasible. As to Dr. Tyson's statement that there is no further need of the use of sodium salicylate since the introduction of the newer preparation, notably aspirin, I am not prepared to endorse his views, although this may be so. I am surprised to learn that Dr. Tyson had used intrarectal salicylate so many years ago, and had I known it I should have incorporated the fact in this paper. Relative to the number of cases of endocarditis following this method of treatment, I have seen only one case in which endocarditis developed during the attack. Occasionally an apparently cured patient with rheumatic fever has been discharged from the hospital and at the next observation some time later, we have found a valvular lesion. It is difficult to determine whether it is subsequent to the previous rheumatic attack or due to a mild infection in the interval between the rheumatism and the appearance of the valvular lesion.

The Production of Senna in the Sudan.—The senna exported from Egypt is gathered from shrubs growing wild in the Sudan and the Red Sea littoral of Arabia. The Sudan variety is the *Cassia acutifolia*, which furnishes what is known as *Cassia angustifolia*, which supplies the senna called Mecca, Arabian or Indian. Senna is gathered once a year, in October, the size and quality of the crop depending on the abundance of the rainfall. The leaves and fruit are allowed to dry on the branches. The product is classified in four grades as follows: whole leaves, half leaves, broken bits and fruit (bean). Suez is the collecting point for both Sudan and Mecca senna. Arabian statistics are not available, but during the year 1912 senna from the Sudan was exported to the value of nearly £10,000 (\$50,000) and in the first half of 1913 to over £6,000 (\$30,000).—*Jour. Roy. Soc. Arts*, June 10, 1914.

enous vaccine in the sense that it was composed of three typical Bordet-Gengou strains isolated from cases included in this epidemic. Table 1 shows the results of the vaccinations. It may be summarized by the statement that *twenty of the 244 cases developed pertussis in spite of the prophylactic inoculations.*

TABLE 1.—PROPHYLACTIC VACCINATIONS (244 CASES)

Vaccine	No. of Inoculations	No. Treated	Pertussis
1	2	35	10
2	3	10	1
3	3	141	6
5	3	58	3
		244	20

Let us examine this table somewhat more closely. It will be seen that Vaccine 1 shows by far the greatest number of failures. Two injections of the vaccine were given in each instance, one of 100 millions, the other of 200 million bacteria. Of the ten cases which developed pertussis, five showed the first symptoms two or three weeks after the first inoculation, one after twenty-five days, one after six weeks, two after an interval of two months or more. In considering the results of prophylactic inoculations, all cases were discarded and not included in the tabulation (Table 2) which shows the development of symptoms of pertussis within two weeks of inoculation.

TABLE 2.—DETAILS OF THE TWENTY CASES DEVELOPING PERTUSSIS NOTWITHSTANDING PROPHYLACTIC VACCINATION

* Received two varieties of vaccine.

When we turn to Vaccine 2 we find rather too small a number of cases to allow of a satisfactory estimate of its worth. Inoculations of 100, 200, and 400 millions were made at three-day intervals. The one case which developed pertussis showed symptoms two and one-half weeks after the first inoculation. It should be mentioned in this connection that five of the cases of this group developed ring-worm and were therefore sent away from the institution. As a result, the period of exposure to infection by pertussis was shortened in these cases.

The results obtained with Vaccine 3 are particularly interesting, as they are so much better than those obtained with the other vaccines. The same doses were given as of Vaccine 2, and with the same intervals. In twenty-four of this group of 141 cases, large doses were given by mistake, namely, 500, 1,000, 2,000 millions. One of these children nevertheless developed pertussis. This case (A. S., Table 2) is of especial interest in that the child received two prophylactic doses of Vaccine 1 about the middle of January, and three very large doses of Vaccine 3 towards the end of February, and notwithstanding this treatment came down with pertussis on March 14; the disease was

exceptionally severe, whooping being continued for a period of ten weeks. The other cases, five in all, developed pertussis three weeks, six weeks, one month, and one about two months following inoculation.

As the result of prophylactic vaccination with these three vaccines it was determined to make a vaccine from cultures obtained from cases in our wards. Dr. Anna Williams was kind enough to prepare a vaccine of this nature as well as to make cultures from the throats of many of the children. It should be emphasized that the typical Bordet-Gengou organisms could be isolated in only five cases out of the thirty cultures taken. In most instances other hemophilic bacilli, frequently the influenza bacillus, were isolated. It may therefore be maintained with some justice that in our cases the symptoms may not in all instances have been incited by the Bordet-Gengou bacillus, and that this accounts for the failures in the use of Vaccine 5. It will be noted that of the 58 cases inoculated with this vaccine three developed pertussis. All these children received 100, 200, and 400 million bacteria. Two of the number began to whoop about one month after vaccination, and one three weeks following the initial injection.

One hundred and thirty children did not receive prophylactic inoculations. This group included a ward of twenty-five infants under the age of 1 year, and another ward of about thirty infants between the ages of 12 and 18 months. These children must be considered separately, as they were at all times in bed, so that the danger of contact infection naturally was far less than in the case of runabout children. Moreover, in the one ward comprising thirty infants, no case of pertussis developed, so that they were not subjected to infection and therefore should not be included among those exposed to pertussis. Only one case of pertussis occurred among the twenty-five infants under 1 year of age. That this case did not lead to further infection shows the difficulties in judging of the results of prophylactic treatment. However, the fact that these infants did not come into close contact, that they were at all times in bed, should of itself exclude them from consideration. It would be a palpable error to compare infection in an infants' ward with that occurring in a ward of older children. This distinction should always be borne in mind in considering the degree of infection in institutions for children. If therefore we subtract these fifty-five cases—the thirty where no infection occurred and where consequently no exposure existed, and the twenty-five where exposure was greatly limited by absolute confinement to bed—we have eighty children who were not vaccinated. Of these eighty, fifty-nine developed pertussis. It will be remembered that of the 244 vaccinated cases, twenty came down with pertussis. There were five cases which cannot be included in the group of either the vaccinated or of the unvaccinated, as they began to whoop within a fortnight of vaccination; the case in the infants' ward constitutes a sixth case which cannot be considered.

It is difficult to determine the degree of exposure of the various children. No doubt it is true that at the very beginning of the epidemic, isolation was less complete and exposure to infection accordingly greater. This period, the early days of the epidemic, corresponds to the time preceding our employment of vaccine. However, granting a certain increased exposure of the unvaccinated at this period, we feel that the disparity in the ratio between the infected and the

non-infected is so marked among those vaccinated and those unvaccinated—among the former twenty out of 244, or one in twelve, among the latter fifty-nine out of eighty, or almost three out of four—that vaccination must have played a rôle. It should be mentioned in this connection that with the exception of the infants' ward, pertussis occurred in every ward in the building, and that quarantine regulations were enforced in the cases of children with suspicious cough or actually manifesting symptoms of the disease.

* First case.

Table 3 shows the development of the cases both according to wards and according to months. It will be noted that in April the number of cases began to diminish. This time corresponds to the period of vaccination. In brief, vaccination was undertaken as follows: The 35 cases were inoculated with Vaccine 1 about the middle of January, and the ten cases with Vaccine 2 about the middle of February. At the very end of March and the beginning of April the large group of 135 cases were treated with Vaccine 3. In other words, prophylactic treatment on a large scale did not exist until the middle or end of April. This date corresponds with the beginning of the cessation of the epidemic. The epidemic may have been waning of its own accord; however, at this time, there was no abatement of pertussis throughout the city. We are therefore of the opinion that the vaccine was of value in preventing infection and in limiting this epidemic, but that it cannot be relied on in each individual case as a prophylactic measure. It would seem probable that there is considerable difference in the potency of various vaccines, and, following the deductions to be drawn from our results, that a polyvalent vaccine of typical Bordet-Gengou bacilli is most efficacious.

ACTIVE TREATMENT

Vaccines were also used in this epidemic in the active treatment of pertussis. As in prophylaxis, four vaccines were employed; however, one of these (No. 2) was not the "Bacterin" mentioned above but the "combined vaccine" of Parke, Davis & Co., which is composed of the Bordet-Gengou bacillus, influenza bacillus, various hemophilic bacilli, streptococci, etc. Of the eighty-five cases of pertussis constituting the epidemic, sixty-five were treated by means of vaccines, and twenty were not vaccinated. No other treatment whatsoever was given to either group of patients. About an equal number of children were treated with each of the four varieties of vaccine; the cases were not selected, a change in the type of the vaccine being instituted whenever about fifteen children had been vaccinated. In some cases two vaccines were made use of just as with the prophylactic treatment.

Table 4 seems of especial interest in judging of the efficacy of the vaccine treatment. This table, it will

be noted, is composed of the twenty severest cases of the epidemic. In compiling this list, we had recourse to the ward charts which showed the number of paroxysms of coughing and attacks of vomiting which each child had by day and by night, and were guided also by the opinion of the resident physician and of the head nurses. After the twenty cases had been selected in this way, a table was constructed to demonstrate their relationship to vaccination. It will be seen that of the total number only two received no vaccine treatment whatsoever. Five received both prophylactic inoculations and active treatment during the course of the disease; five were inoculated with two varieties of vaccine. This list, which is essentially a list of therapeutic failures, contains representatives of all four vaccines, but it will be noted that, as in the case of prophylactic vaccination, Vaccine 1 makes the poorest showing. It would seem that this table requires little comment. It clearly demonstrates that the use of vaccines in this epidemic did not lessen the severity of the disease. We should add that pertussis in New York City as well as in our institution was characterized this year by its mildness. Indeed, we did not experience any fatality and but two cases of pneumonia. In an epidemic of this nature it would evidently be less valuable to judge the results of treatment by considering the number of mild cases, than by noting those of exceptional severity. This is all the more pertinent in a disease having the irregular symptomatology of pertussis, where mild cases can be differentiated with difficulty from the common cough of non-specific origin. In the tabulated cases it cannot be contended that treatment was not begun sufficiently early, as the first vaccination was in almost every instance administered during the first week of the disease. This is as early as we can hope to be able to employ vaccines in the course of any disease. Moreover, a glance at Table 2 (composed of cases which developed pertussis notwithstanding prophylactic inoculation) shows that where these early inoculations failed to ward off the disease, its severity was not mitigated; that in numerous instances not only did the vaccine fail to prevent infection, but that it did not shorten or mollify the course of the illness. In no instance, however, did any harmful local or systemic reaction follow the injection of vaccine. In this connection we may add that all attempts to employ the vaccines for diagnostic purposes proved futile, whether as a cutaneous, intracutaneous or subcutaneous test.

TABLE 4.—VACCINATION IN RELATION TO THE TWENTY SEVEREST CASES

Case	Vaccine Prophylactic	Vaccine Curative	Case	Vaccine Prophylactic	Vaccine Curative
1	0	0	11	0	1

9	0	0	19	0	1
10	0	1	20	3	0

The complement-fixation test of the serum was carried out on ten cases, using the Bordet-Gengou bacillus as antigen. These tests were made by Miss Olmstead of this laboratory, whom I wish to thank in this connection. The number of cases is far too few to allow of a statement of the value of this reaction in pertussis. In general, however, the results would seem to show that this reaction is present for some

months after the cessation of all symptoms. Its chief interest is in connection with the still mooted question of the specificity of the Bordet-Gengou bacillus. It is for this reason that the cases are appended in a table (Table 5).

* Pertussis doubtful.

CONCLUSIONS

We have reported on the use of a series of vaccines in an epidemic of pertussis occurring in an institution for young children. An occasion of this nature furnishes exceptional opportunity to observe this disease, which is characterized by an indefinite onset and an irregular course, and is furthermore rarely adaptive to hospital study.

What deductions are to be drawn from the observations which we have recorded? It would seem clear that none of the four vaccines, including an autogenous strain, was of value in curing or tempering the disease in the epidemic which existed in our institution. That this failure was not due to tardy inoculations is emphasized by the circumstance that many of the severest cases received not only early active treatment but also prophylactic vaccination. No other conclusion seems possible from a review of the epidemic of 85 cases, and a comparison of the severity of the disease among the vaccinated and the unvaccinated. This opinion is based solely on our experience in this epidemic and does not preclude the possibility that a different dosage of vaccine, or treatment with a modified vaccine, may not prove to possess curative properties.

The use of the vaccines in prophylaxis seemed by analogy to offer greater promise, in view of the established fact that other vaccines, for example the typhoid vaccine, possess prophylactic although no curative power. This seems to some extent, although to a far less degree, to be true of pertussis vaccine. In view of the fact that twenty children developed pertussis in spite of the prophylactic treatment, we cannot compare its protective value to that of typhoid vaccine. However, the proportion of unvaccinated children who developed pertussis so greatly exceeded the number of the vaccinated who developed the disease, that we conclude that the vaccine has protective value in a certain percentage of cases, and that it should be employed in institutions and in families to prevent the spread of this infection.

16 West Eighty-Sixth Street.

ABSTRACT OF DISCUSSION

DR. JOHN ZAHORSKY, St. Louis: About two years ago I reported a series of forty cases of pertussis treated by vaccine in private practice. Dr. Hess has spoken of the Infants' Asylum children as being ideal for treatment. There is one objection to that; infants in asylums have much less immunizing power in themselves. They do not resist infection so well as children in families. Their response is much slower, and I do not think we can get as good results as in private practice. I am glad to hear that the effect of the prophylactic

injection was so marked. I was still in doubt as to whether we could expect a prophylactic injection to prevent whooping-cough. Bordet has shown how very difficult it is to immunize against this infection. There are some children who do become immunized to their own infection rather quickly. Others have great difficulty in becoming immune. There is a certain group of cases, those in children who have good health in every way, children who rapidly respond to infection, in which vaccines are of curative value. I think I have clearly shown that in about half the number of cases, if one, two or three injections are given at the height of the disease, thereafter the disease becomes much milder; not necessarily shorter, because after all it takes time to become immune to the pertussis bacillus. I used the vaccine last winter in fifty cases. Again and again we get such nice results from its use that it should be added to our stock of therapeutic aids in whooping-cough.

DR. T. C. McCLEAVE, Berkeley, Cal.: I have had a limited experience in the use of pertussis vaccine; yet it has taught me clearly that Dr. Hess is right. I have not been able to persuade myself that the vaccine was of the slightest curative value. Some of the mothers have thought so, but I was not able to corroborate their opinion. In a little epidemic at home I have had opportunity to use it in a number of families. I have vaccinated all of the children, the sick ones for curative and the well ones for prophylactic purposes. It was my experience that all of these children who were prophylactically treated and yet remained in association with the children with whooping-cough, failed to take the disease. That is, the prophylactic treatments were 100 per cent. effective, in only six or eight cases, it is true. I think the method is of value, and should unquestionably be used. This treatment is interesting to me as a private practitioner, and I believe it would be peculiarly valuable when I have particularly good control of my patients, because in the case of children continuously under my observation I intend to revaccinate from time to time and hope to prevent them having whooping-cough during their childhood. I hope to be able to determine the duration of immunity from pertussis vaccine by a method similar to the von Pirquet method for tuberculosis and the Gay skin-test for typhoid. Possibly next year I will have some information. I merely mention it as of interest. We may be able in children under our control at least to greatly reduce the susceptibility.

DR. S. M. HAMIL, Philadelphia: I have not used vaccines in the treatment of whooping-cough. A few years ago I made a complete study of the literature of pertussis, and I discovered at least 100 specific drugs recommended for the treatment of this disease. Quite interesting was the fact that some of these remedies were advocated by men of undoubted standing. Series of cases were reported in which the results were directly attributed to these various drugs. I remember, for instance, that Moncorvo reported glowing results in a series of cases from the direct application of aristol. Later he reported on it unfavorably. Where are those specific remedies now? Entirely forgotten. Why were they recommended by able men? Merely because it is so hard to determine the results of treatment in pertussis. An untreated case of great severity may suddenly develop sufficient immunity to change the entire nature of the case, even to the extent of producing a so-called abortive attack. The effect of drugs in such a case can only be misinterpreted. Therefore, we should interpret the results of vaccine treatment very cautiously. We should remember also that its application is painful, that vaccines are expensive and not free from danger. I have known of a number of instances in which alarming symptoms have followed their use. There is just as much evidence against the value of vaccines as there is in their favor.

DR. D. L. RICHARDSON, Providence, R. I.: This subject is very important, particularly from the point of public health. Will Dr. Hess explain whether in the class of cases in which he used vaccines they were infants or small children that were in bed? Were they put to bed in the attempt to control the disease, and in the non-immunized class were they older chil-

dren in which the question of personal contact was greater? That would bear materially on his results. Perhaps I did not clearly understand. If this vaccine does immunize, it will be of great value in the future in controlling the disease. The development is so insidious that the damage is done much as in measles, but in a more subtle manner.

Dr. KATE C. MEADE, Middletown, Conn.: We have just had two epidemics—one of whooping-cough and one of small-pox. We had a severe epidemic among the children of the well-to-do. Having heard of the results of this treatment from a friend in St. Louis, I asked Dr. Fisher to make me some autogenous vaccine for pertussis. The first vaccine made I think was weak. I tried it on twelve children. In many families the mothers were intelligent and able to interpret conditions. In each case it has been the oldest child who has brought the disease into the family—the child who has been in school. That child I never gave vaccine to, but immediately began on the small children. In one case I began with 150,000. I gave the vaccine in one case every day for three days, in another case each day for two days. In one case in which I knew a baby was coming into a home, and I thought it would be rather difficult to give a new baby vaccine, I gave a little boy six doses altogether, and no other medicine. In every one of these cases the disease was stopped within eight or ten days. A little cough was left, but no whooping and no vomiting or spasmodic attacks. The older children continued to cough, but did not reinfect the smaller children. The new baby came and did not take the whooping-cough. We have been using Dr. Fisher's vaccines a great deal—mostly autogenous. I think she has great skill in preparing them. In several children we used a combination of our vaccine and a stock coryza vaccine. My twelfth case was a man, aged 76, who had typical pertussis and pneumonia. I was interested, when visiting the New York laboratory, to find they are having difficulty in separating some of their strains from that of pneumonia. In the case of this man, I gave him an autogenous strain of his own pneumococcus. He recovered remarkably, both from the pneumonia and the pertussis.

Dr. EDWARD S. REIMER, New York: Will Dr. Hess say at what stage in these various cases treatment was instituted? In my own limited experience, by starting in early we get better control of the cases, and much better results.

Dr. FRANK W. PINNEO, Newark, N. J.: Dr. Meade's case in a man of 76, reminds me of an old lady who contracted whooping-cough last summer from a little child. While I ardently believe in vaccines, I did not use any in her case. Perhaps it was wise, because she contracted pneumonia and became very ill, but finally made a perfect recovery. We need greater knowledge about vaccines before laying down rules for their therapeutic use, and in institutions such opportunities as Dr. Hess has embraced are offered, while for private practice we may await further knowledge.

Dr. HENRY HEIMAN, New York: It is extremely difficult to differentiate between true pertussis and those cases of bronchopneumonia of influenzal origin with a distinct pseudopertussis cough. In these latter cases it is extremely difficult for little children to expectorate this sticky material from the smaller bronchi. We have to be very careful in making a differential diagnosis.

Dr. HARRY LOWENBURG, Philadelphia: I think Dr. Hess has not entirely proved his case. It is a remarkable thing that prophylactic cases should be so good and results with treatment should be so poor, especially in cases in which tremendous doses are given. It does not seem likely that a remedy that would prevent would not also cure. Will Dr. Hess state just what the amount of contact was in these cases that did not develop? That these children did not develop a cough was no proof that the vaccine was effective. I should like to know whether opportunity for contagion was very great.

Dr. ALFRED F. HESS, New York: Dr. Zahorsky spoke about the deficient immunizing power of children in institutions. I do not think that has ever been proved. That they are more susceptible to infection is true. If you take 100

persons in the almshouse, however, and immunize against typhoid, they will be immunized as thoroughly as 100 private persons. Children in institutions form antibodies, and they can be immunized just as well as children outside of institutions. With regard to a skin reaction with the vaccine, I may say that I tried it, but had no success. There was an unreliable local reaction, but no general reaction. I did say—perhaps I did not make myself clear—that I excluded from consideration all patients confined to bed. All the cases cited were ambulatory. There were two wards of infants in bed. One was a ward with twenty-five children in which there was one case of pertussis. It did not spread because there was no contact. The other was a ward with thirty children between 12 and 18 months old. As there were no cases in that ward, and no exposure to infection, they were excluded. The entire report is of children between the ages of 2 and 6, all runabouts. This answers the question raised by Dr. Lowenburg as to the danger of exposure. Whooping-cough occurred in every ward except the one which I mentioned, although the degree of exposure may have been somewhat different. Nevertheless, so far as we can tell, there was exposure in every ward. The vaccine was given in the early stages—as soon as a child was reported to have whooped, vaccine was given. I do not believe it can be given earlier than in an infant asylum where there is a resident physician. Dr. Heiman has raised the question of influenzal infection. Influenza was found by culture in our laboratory in a large number of these cases. The Bordet bacillus was also found. With regard to curative and prophylactic results I do not believe this prophylactic result is especially brilliant. It failed in 10 per cent. of cases. The result is not nearly so good as with some other vaccines. For instance, typhoid vaccination would be considered poor in results with 10 per cent. of failures. Compared to results in those not vaccinated, however, it is very good. It is very much easier to prevent a disease than to cure it after a considerable infection has occurred.

A NOTE ON THE PREPARATION OF BACTERIAL VACCINES* WILLARD J. STONE, M.D. TOLEDO, OHIO

The work of Vaughan, his associates and others interested in protein poisons has established the relationship of these substances to local and general anaphylactic reactions. Some of the reactions following the injection of bacterial vaccines are undoubtedly due to extraneous medium proteins which have not been removed from the bacterial suspensions in the prevalent process of manufacture.

Since in the preparation of bacterial vaccines we are concerned only with the immunizing properties of the cellular proteins, it should be our aim to reduce, so far as possible, the amount of extraneous proteins in the method employed. Most of the commonly employed mediums used for the growth of bacteria contain protein substances. When the bacterial growth is washed or scraped from the surface of an agar slant, or separated by centrifugation from a bouillon culture, the soluble excretory products of the bacteria, as well as soluble medium products are present in considerable amounts. If such suspensions in salt solution are standardized and used as vaccines, the local and general reaction which follows is apt to be relatively severe, depending on how much extraneous protein happens to be present, and on how soon after preparation the product is injected.

* Read before American Association of Immunologists, Atlantic City, N. J., June 21, 1914.

Since the suggestion was made to me by Dr. Carl C. Warden, who at the time was working with gonococcic vaccines, I have thoroughly washed all bacterial suspensions used in the preparation of vaccines, in the high-speed centrifuge, until the supernatant salt solution (0.45 per cent.) no longer gave a biuret test. The ninhydrin reaction has not been used because of its greater expense. Two or three such washings in the centrifuge will usually suffice to remove most of the extraneous protein. The vaccines so prepared I have called "washed vaccines," since such suspensions are practically free from all unnecessary and undesirable proteins. Washed vaccines possess the cellular elements necessary to immunization, but are free from those proteins which, in many preparations, have been responsible for relatively severe local and general reactions. Washed vaccines are much more suitable for intravenous administration.

Such washing is applicable in the preparation of all bacterial suspensions for vaccine purposes, with the exception of such fragile organisms as the pneumococcus and the gonococcus, the ordinary strains of which autolyze rapidly. Recent work by Sobernheim, by Seligmann and by Warden with more stable mutation forms of organisms offers the hope that less autolysis will take place on thorough washing and that these mutation suspensions may be handled in a manner similar to the suspensions of the more stable organisms.

For purpose of standardization, a suspension of the living, rather than dead, washed organisms is employed. The following method, which is preferable to the blood-cell-slide method of Wright because of greater accuracy, was suggested some years ago by Dr. L. H. Spooner of Boston, and has been used by me as a routine procedure with satisfaction: A small amount of the suspension is drawn into an ordinary erythrocyte mixing pipet, diluting 1:100 with a fairly deep-colored, thoroughly filtered, aqueous carbolthionin stain (the phenol (carbolic acid) content is 0.5 per cent.). The suspension in the counter is well shaken to secure even distribution of cells and a small drop placed on the shallow blood-platelet counting chamber of Helber-Zeiss. The organisms in twenty-five small fields are counted, and the sum divided by 25 to obtain unit value. The number so obtained is multiplied by the dilution 100, by 50 the depth of the chamber, by 400 the number of small squares per cubic millimeter and lastly by 1,000 to convert to cubic centimeters. For example, if forty bacterial cells are counted in twenty-five small squares, the unit value per square would be 1.6, multiplied by 100, by 50, by 400 and by 1,000 or 3,200 millions per cubic centimeter of suspension.

Observation Must Precede Inference.—Take a group of students who are working at physical diagnosis and it is a constant struggle to keep them making observations and not giving inferences—usually from insufficient observation, if from any at all. No pains are too great to hammer home into the mind of every student the importance of keeping these two processes separate and not taking up the second until the first is as complete as he can make it. It is just as important for the practitioner as for the student, except that in the latter we are trying to form correct habits; the practitioner should have them.—Thomas McCrae, M.D., in the *Canadian Med. Assn. Jour.*

CANCER OF THE PROSTATE*

BERNARD FRANCIS McGRATH, M.D.

ROCHESTER, MINN.

The facts that the general subject of cancer presents even to-day one of our most serious and unsolved problems; that cancer of the prostate is a comparatively frequent and exceedingly distressful form of the disease; and the probability that by a more widespread application of the present available knowledge of this pathologic process the prevalent high percentage of disability and death would be considerably diminished, are advanced as sufficient reason for presenting a discussion of the subject with a contribution of data to the fund of experience.

The pathogenesis of cancer of the prostate is still a debatable question; the frequency of its occurrence, the usual sites of its original focus, its mode of extension and metastasis, are phases of the subject which are reasonably supported by facts.

This paper is based, first, on the examination of a series of 716 prostatic specimens removed at operation in the Mayo Clinic from Oct. 28, 1904, to June 1, 1914; secondly, on the pathogenesis of epithelial tumors of the breast, as view by MacCarty; and thirdly, on a review of the literature.

PATHOGENESIS

The opinions of various investigators with regard to the pathogenesis of cancer of the prostate are not uniform. The cause of this lack of uniformity seems to be due, at least in a great measure, to the different points of view from which the pathologic process is viewed.

Some authors maintain that cancer does not begin in a hypertrophic portion of the gland, that its presence here is an invasion from a focus situated elsewhere in the organ, usually in the posterior lobe. Others state that cancer occurs as an almost imperceptible transition from a benign adenoma. Still others, disregarding as unessential the consideration whether the associated process be one of general hypertrophy, adenoma or other pathologic condition, view, apart from its causation, the pathogenesis of prostatic cancer, likewise of cancer in general, as fundamentally a question of the histogenesis of epithelial cells.

A summation of the evidence adduced from the various investigations emphasizes the fact that cancer occurs in the atrophic, the apparently normal and the hypertrophic prostate. In the light of this accepted fact is seen an indication that involved in the development of the cancerous process there is a study far more basic than what is comprehended in a consideration of associated pathologic conditions. Again, the weight of evidence seems to prove that the disease begins most frequently in the posterior lobe of the gland. This seeming selectiveness of the process, however, is no more explicable in the prostate than are similar phenomena in other organs. The incident of original focus is aside from the underlying principle of pathogenesis, as advanced in the theory of the histogenesis of epithelial tissue.

CANCER OF THE BREAST

In 1898 Albarran and Hallé,¹ in an oft quoted and adversely criticized treatise under the caption, "Hypertrophy and Epithelial Neoplasms of the Prostate," direct attention to the "remarkable analogy between the hypertrophied prostatic gland and the mammary gland affected with benign tumors, or with those epithelial and interstitial lesions, which are still wrongly classified among the benign neoplasms and the chronic inflammations."

In 1907, Ewing,² discussing "Cancer Problems," stated that "inflammatory hyperplasia passes by insensible gradations into neoplastic growths." During the past five years, MacCarty³ has contributed several papers to the subject of cancer of the breast. This author was stimulated to undertake an extensive investigation of the epithelial growths of the mammary gland because of inability to harmonize his daily observations with the prevalent views of the pathogenesis of these tumors and the apparently redundant, diverse and unintelligible classification of the pathologic processes.

With the purpose of endeavoring to determine an analogy between the pathogenesis of cancer of the mammary gland, as advanced by MacCarty, and the pathogenesis of cancer of the prostate, I undertook the examination of this series of prostatic specimens. A brief summary of MacCarty's investigation of epithelial growths of the breast follows:

Fig. 1.—Breast; acinus showing primary epithelial hyperplasia (MacCarty).

Fig. 2.—Breast; acinus showing secondary epithelial hyperplasia (absence of inner row of cells and hyperplasia of outer row of cells in lumen [MacCarty]).

The normal acinus of the mammary gland is lined with a single row of cylindrical epithelial cells, which are the differentiated, functional cells of the organ. These differentiated cells arise from the stratum ger-

Fig. 3.—Breast; acini showing secondary hyperplasia and confusion of line of demarcation between acinus and stroma (MacCarty).

At the beginning of this work the hypothesis was formulated, that the cells of cancer are the direct offspring of cells normally present in the acinus of the breast, and that they are derived neither from the differentiated cells through metaplasia, nor from the natal or postnatal rests, according to the views attributed to Cohnheim and Ribbert. The investigation has been pursued on the foundation constructed by authoritative embryologists; personal speculation has been scrupulously avoided and notes of conditions have been confined strictly to the morphologic evidence presented by epithelial tissue under the microscope. At the present period of this long investigation, MacCarty states that his earlier observations have been confirmed, and that his view of the origin of cancerous cells in the breast is no longer a hypothesis, but a demonstrable fact.

minativum, which is usually undiscernible until some stimulus causing hyperplasia is present. Then the germinative layer appears in the acinus as a second row of cells which adjoins immediately the surrounding stroma. For descriptive purposes these cells are termed the outer row and are described as the undifferentiated or partially differentiated precursors of the

3. MacCarty: Tr. of Surg. and Gynec. Assn., 1910; Surg., Gynec. and Obst., October, 1913, p. 441; Surg., Gynec. and Obst., March, 1914, p. 284.

specific functional cells. The morphologic appearance of these cells of the outer row differs from that of the differentiated cells, which now form and are termed the inner row. In the presence of an excessive or abnormal stimulus the cells of the outer row become

Fig. 5.—Breast; acinus showing secondary epithelial hyperplasia with irregularity of nuclei (MacCarty).

hyperplastic and partially or completely fill the acinus. In this event, the functional cells are present, exfoliated or absent. Furthermore, the undifferentiated cells are observed not only intra-acinic, but also extra-acinic, situated in the stroma. Therefore, some microscopic fields present both rows of cells, differentiated and undifferentiated, distinct in the acinus; other fields

Fig. 6.—Breast; tertiary epithelial hyperplasia, showing irregularities of nuclei—cancer (MacCarty).

show a definite predominance of intra-acinic, hyperplastic undifferentiated cells; and in still others, both intra-acinic and extra-acinic hyperplastic undifferentiated cells are seen. In some fields in which the inner row of functional cells are exfoliated or absent, and

the undifferentiated cells of the outer row hyperplastic, the line of demarcation between the acinus and the stroma is observed obliterated, totally or in part, and the latter cells are noted also in the stroma. The facts that epithelial invasion of stroma is the accepted histologic picture of cancer; that in these observations the epithelial cells in the stroma are morphologically indistinguishable from the hyperplastic undifferentiated cells of the acinic outer row; and finally, that the latter cells represent the normal precursors of the functional cells in the stratum germinativum, seem to lead logically to the deduction that *the cancerous cells of the mammary gland are the direct, immediate descendants of the undifferentiated cells of the germinative layer*, consequently, that the hypothesis of "embryonic rests" is not essential for the explanation of cancer in this organ.

For the sake of simplicity in studying the mammary epithelial tumors, the following classification is based on the observations cited above: The pathologic processes involved in these epithelial growths are designated, (1) primary hyperplasia; (2) secondary hyperplasia; (3) tertiary or migratory hyperplasia. In pri-

Fig. 7.—Normal prostatic epithelium.

mary hyperplasia, both rows of cells, the inner, differentiated, and the outer, undifferentiated, are present and concerned in the reaction; in secondary hyperplasia, the outer row, undifferentiated cells, are excessively proliferated (cancer?); in tertiary hyperplasia, the hyperplastic undifferentiated cells of the outer row are also present in the stroma (cancer).

The probability is advanced that, viewed in the light of these studies, the old criterion for determining cancer histologically, namely, the permeation of the "basement membrane," may be erroneous, consequently, that we may be compelled to view the condition of secondary hyperplasia as possibly malignant before invasion of tissue has occurred.

CANCER OF THE PROSTATE

In examining the prostatic specimens of this series for the purpose of seeking an analogy between the cancerous process in this gland and that noted by MacCarty in the breast, the following observations have been made:

The normal acinus of the prostate is lined with a single or an imperfect double layer of columnar epi-

thelial cells. These are the differentiated or specific functional cells of the gland. In the examination of the pathologic specimens, these functional cells are seen frequently in a state of excessive proliferation, forming projections in and bridges across the acini. There is observed also partial or complete exfoliation of the same cells with the formation of cysts, which are empty or contain accumulations of the cells in varying degrees of degeneration. Some fields are noted in which the acini present not only the proliferated functional cells, but also, outside these and immediately adjoining the stroma, another row of cells, which are morphologically dissimilar to the inner row of differentiated cells. Other fields contain acini with functional cells present, exfoliated or absent, and the lumina partially or completely filled with the hyperplastic undifferentiated cells of the outer row. Still other fields are seen in which these hyperplastic cells of the outer row are both intra-acinic and extra-acinic, consequently presenting epithelial invasion of tissue, the accepted picture of cancer. Furthermore, what is impressive, the three conditions just described have been observed together in the same microscopic field.

Fig. 8.—Normal prostatic epithelium.

An analysis of this comparative study of the prostate and the mammary gland indicates that an analogy exists between the microscopic pictures of epithelial changes in the cancerous process of both organs. The analogy being accepted, it follows that this study of the prostate adds further support to MacCarty's deduction, drawn from extensive observations on epithelial growths of the breast. If adequately prolonged and comprehensive investigations in the future positively confirm the present view of the latter author, it may be stated of the prostate that, whatsoever the associated pathologic condition or wheresoever the original focus, these are factors which are unessential to the process of cancerous development; that this is essentially a process of epithelial hyperplasia, involving the above-described undifferentiated cells, in a state of reaction to an abnormal irritant. Furthermore, for the pathogenesis of cancer it would not be necessary to assume the theory of "embryonic rests."

Frequency.—Statistics indicate that we are indebted to the investigators of the past half century for the existing knowledge of cancer of the prostate. The

first useful statistics were compiled by Thompson⁴ (1854) who cited 18 cases from the English and the French literature. Wyss⁵ (1866) reported 28 cases, including Thompson's; Socin⁶ (1875), 50 cases; Kapuste⁷ (1885), 54 cases; Engelbach⁸ (1888), 144 cases; Wolff⁹ (1899), 110 cases. Since 1902, numer-

Fig. 10.—Normal prostatic epithelium, proliferating and projecting in masses in the lumen of the acinus.

ous reports of malignant prostatic conditions have been contributed. It is the statistics of the more recent writers, however, which, although varying within somewhat wide limits, afford us the nearest approximation to the truth with regard to the frequency with which cancer occurs in the prostate.

In 500 cases of prostatic obstruction, Young⁶ found cancer in 20 per cent. The same author states that about one out of every seven enlarged prostates after 50 years of age is cancerous. Albarran and Hallé noted 14 per cent.; Walker,⁷ 16.5 per cent.; Wilson and McGrath⁸ (1911), 468 reexamined prostatic specimens

present series of 716 specimens (including the 468 cases reported by Wilson and McGrath in 1911), 12.28 per cent.† are cancer.

Age.—One patient was between the ages of 40 and 50. Seventy-eight per cent. were between 60 and 80. Other investigators have found about 68 per cent.

Fig. 12.—Cystic acini, showing two rows of cells, inner and outer row, similar to pictures seen in breast in primary hyperplasia.

between the ages of 50 and 70. Wolff reports six patients under 40; one, 29 years of age.

Mode of Involvement.—Cancer of the prostate is primary in the great majority of cases. The gland is involved secondarily by adjacent cancer or through metastasis by way of the blood-stream. Rectal ulceration is the most frequent source of secondary prostatic cancer from contiguous structures. About one-half the cases of secondary involvement are metastatic from remote organs.

Site of Origin.—The most commonly ascribed site of the original focus in primary cancer of the prostate is the posterior lobe; but its presence in the lateral and middle lobes has been noted by some authors.

Fig. 13.—Cystic acini, showing two rows of cells, inner and outer row, similar to pictures seen in breast in primary hyperplasia.

Growth.—The cancerous process has been observed to involve the entire prostate symmetrically and rapidly, but the consensus of investigators' opinions is that, in by far the large proportion of cases, cancer of this gland is limited, occurring as one or several

little nodules and of slow growth. Consequently, gross serial sections of the specimen and microscopic examination of every doubtful area are essential for the diagnosis in the great majority of cases. Failure to appreciate this point, also neglect to examine the posterior lobe, are the probable cause of statistics with low percentage of cancer, likewise of inadequate treatment and erroneous prognosis.

Extension.—In the extension of prostatic cancer the fascia of Desnonvillers, also the fibrous capsules, both of the prostate itself, and of hypertrophied spheroids, lobules or lobes, are accredited with an essentially important rôle. Young emphasizes this point. Cuneo and Veau¹⁰ have shown that the fascia of Desnonvillers is a prolongation downward of the peritoneum in fetal life, which projecting in a plane between the prostate and the seminal vesicles in front, and the rectum behind, by virtue of its reduplication doubly inhibits the spread of cancerous cells posteriorly. Consequently, ulceration of the rectum is infrequently seen and periprostatic structures are quite effectively guarded. The tendency, then, of the cancerous process is to extend upward to the region of the ejacula-

Fig. 15.—Normal epithelium in acinus, acinus with exfoliation of differentiated cells, acinus with some exfoliated differentiated cells and invasion (?) of stroma by hyperplastic cells of the outer row.

tory ducts, between the fascia of Desnonvillers posteriorly and the trigone anteriorly. Young maintains that the mucosa and submucosa of both urethra and bladder are very resistant to the malignant invasion. On the other hand, von Frisch¹¹ notes extensive involvement of both these structures. The seminal vesicles are frequently involved, and the growth may extend along the ureters, causing complete obstruction, even rupture. Extension upward for a long distance within the vasa deferentia, without apparent involvement of the outer walls, may occur (Young). Cases noted by von Frisch were: Growth into rectum with subsequent extensive involvement of the sacrum. Growth through the obturator foramen and between the adductors of the thigh. Once the capsule is permeated, the cancerous process spreads extensively.

Metastasis.—This occurs in bones, lymphatic glands and internal organs. Important to be emphasized is the fact that, whereas the primary cancer of the pros-

10. Cuneo and Veau, cited by Bryan: *Lancet-Clinic*, April 20, 1912, p. 433.

† In the last 248 cases of this series only the specimens already diagnosed cancer were studied. It is probable that reexamination of the remaining specimens will increase the percentage of malignancy.

tate is usually small, metastases from it are commonly extensive. The most frequent sites are the skeletal bones and the lymphatic glands. Visceral metastasis is comparatively infrequent, probably occurring in about 25 per cent. Kaufmann¹² remarks the infrequency of glandular metastasis from prostatic cancer compared with that from cancer of other structures. In 100 collected cases this author found involvement of the pelvic glands 27 times; iliac, 24; inguinal, 16. Young, whose figures agree with those of Kaufmann as to the involvement of the pelvic glands, says: "It shows the fact that one should not expect enlarged glands before making a diagnosis of carcinoma of the prostate." Blumer¹³ states that cancer of the prostate gives rise to metastasis in bones in a much larger proportion of cases than any other form of cancer—probably in two-thirds of patients in whom it is allowed to run an unobstructed course. Von Recklinghausen¹⁴ emphasizes the fact that the cancerous focus in the prostate is, in comparison with the advanced foci in the bone, small and insignificant. The author directs attention to the analogy between metastasis in bone from a small nodule of cancer in the female

Fig. 16.—High power of acinus in Figure 15, showing both exfoliated differentiated cells and hyperplastic cells of the outer row.

breast and that from cancer of the prostate, and gives warning to suspect these sources in case of severe pain in the spinal column without evident cause. Blumer advises similarly in case of spastic paraplegia—involvement of the spine—and apparent osseous tumors in flat and long bones. In the thyroid, likewise, certain forms of malignant tumors occur which present entirely analogous relations, and such growths may be so small as to escape attention (von Eiselsberg¹⁵). The metastasis in bone is more or less general, its transmission is vascular rather than lymphatic and nearly always originates in the medulla—rarely beneath the periosteum (Blumer).

SUMMARY

1. An analogy exists between the microscopic fields of epithelial changes observed in cancer of the pros-

tate and those of the mammary gland, as presented by MacCarty.

2. In the undoubted histologic picture of cancer, both organs present in the stroma migratory epithelial cells which are morphologically indistinguishable from the hyperplastic undifferentiated cells within the acinus.

Fig. 17.—Acinus in Figure 15, in which there are exfoliation of differentiated cells, hyperplastic cells of the outer row and immediate peri-acinus invasion of stroma by hyperplastic cells of the outer row.

3. According to the studies of MacCarty, these intra-acinic, hyperplastic, undifferentiated cells represent the precursors of the specific functional cells of the gland; consequently, the positively cancerous cells are the direct, immediate descendants of those which become the differentiated cells under normal conditions.

4. This analogy between the prostate and the mammary gland being accepted, further support is

Fig. 18.—Acinus showing the two rows of cells, acinus showing the hyperplastic cells of outer row, completely filling the lumen.

added to MacCarty's deductions, drawn from extensive studies of the breast. And, if adequately prolonged and comprehensive investigations in the future confirm the present view of the latter author, then it may be stated of prostatic cancer, as well as of cancer in general, that the process is fundamentally one of

epithelial hyperplasia of the above-described undifferentiated cells, in a state of reaction to an abnormal irritant; furthermore, that for the pathogenesis of cancer it would not be necessary to assume the theory of "prenatal or postnatal rests."

5. Cancer of the prostate is a comparatively frequent disease after 50 years of age.

6. The process usually begins in the posterior lobe and occurs more commonly as a small nodule or

Fig. 20.—Same as Figure 19, showing in upper acinus primary and secondary hyperplasia; in lower acinus, secondary hyperplasia.

nodules of slow growth; consequently, *careful investigation of the posterior lobe, gross serial sections of the specimen, with microscopic examination of doubtful areas, are essential for diagnosis in the majority of cases.*

Fig. 21.—Same slide as Figures 18, 19 and 20, showing hyperplastic epithelial cells in the stroma, probably a lymphatic space (tertiary epithelial hyperplasia, or cancer). The cells are morphologically indistinguishable from the intra-acinic hyperplastic cells of the outer row (secondary hyperplasia).

7. The fascial strata associated with the prostate seem to be quite effective barriers to the progress of the disease.

8. The tendency of extension of the cancerous process is upward to the region defined by the fascia of Desnonvillers posteriorly and the trigone anteriorly, and then beyond this area.

9. Metastasis affects bones, lymphatic glands and internal organs. The cancerous focus in the prostate may be, and commonly is, insignificant, while the metastasis in bone is extensive. Similar relations have been observed with small cancerous nodules in the female breast and the thyroid. Manifestations in bone, with cause obscure, should direct attention to these observations.

10. Involvement of lymphatic glands is not a dependable factor in diagnosis, since metastasis may be present in the skeletal structure and these glands apparently unaffected.

A COMMON MECHANISM FOR MOST INJURIES OF THE SHOULDER REGION

SUPPORTED BY THE RESULTS OF TREATMENT, INCLUDING FORTY-NINE OPERATIONS *

T. TURNER THOMAS, M.D.
PHILADELPHIA

During the past six or seven years I have been making a study of a series of traumatic conditions affecting the shoulder and arm, and have presented a special study of each condition. The views expressed have been radical because they were based on a new

Fig. 1.—Humerus at normal limit of abduction. Leverage effect begins when capsule tears, which usually occurs at the glenoid or humeral attachment. Each of the diagrams on effects of hyperabduction on skeleton of shoulder region includes, except Figure 10, the clavicle, scapula, upper half of the humerus and capsule of the shoulder-joint.

conception of the etiology. The clinical experience by which they were supported was small because the methods of treatment were new and because the "let alone treatment" has been the rule in most of these cases. Of one of these conditions, recurrent dislocations of the shoulder, I recently reported the results of operation on eighteen shoulders, the largest number previously reported by one writer being four. I have since operated on four more. My particular purpose, now, is to show that they can be traced to an essentially common cause, and that the views offered have a rational anatomic basis and are justified by the results of treatment. It is important to bear in mind that we are dealing here with conditions that have always been the subject of much discussion and conjecture.

The conception of the anatomic basis of these conditions was of gradual development. For more than ten years I had been working on the applications of anatomy to surgery, with the cadaver as the basis of the work. There is no essential difference in the signs

* Read before the Section on Surgery, General and Abdominal, at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

* Because of lack of space this article is abbreviated in THE JOURNAL. The complete article appears in the Transactions of the Section and in the author's reprints. A copy of the latter will be sent by the author on receipt of a stamped addressed envelope.

obtained in a dislocation of the shoulder on the cadaver produced by hyperabduction, and in the usual dislocation of the shoulder in life, which is generally admitted to be due to hyperabduction. The best knowledge we have of dislocations of the shoulder and hip has come from studies of cadaver dislocations. If methods of treatment founded on such studies produce distinctly better results than those in vogue and not supported by such work, then they should and, I believe, will receive the consideration of the profession. For a

Fig. 2.—Capsule torn extensively from glenoid margin, head pried out of socket and humerus moved downward on edge of acromion. In recurrent dislocations, gap between torn capsule margins is later bridged across by new cicatricial capsule.

Fig. 3.—Capsule torn from humeral attachment in whole circumference, taking with it a fragment of greater tuberosity. This lesion is sometimes responsible for flail shoulder-joint.

fuller discussion of the various phases of the work, I must refer the reader to previous papers, references to which will be given later. My object now is to present a perspective outline of the whole subject, and this demands brevity.

It is of much importance to know the mechanism by which an injury to the skeleton is produced. We know very little about this whole subject. Concerning

Fig. 4.—Upward dislocation of outer end of clavicle from hyperabduction.

Fig. 5.—Anterior dislocation of shoulder with arm at side. Upper portion of capsule unruptured.

Fig. 6.—Fracture of surgical neck of humerus. Upper end of lower fragment displaced upward, forward and inward, like the head of the humerus in anterior dislocation of the shoulder.

Fig. 7.—Fracture of middle of clavicle from hyperabduction. Outer fragment forced downward and inward like acromion in Figure 4.

fractures and dislocations, even our largest systems of surgery have little more to say than that they are due to direct or indirect violence. We cannot rely much on the statements of the patients as to how the force was applied. They were too excited at the time and usually do not know until later where the force was expended, and then only in a very vague way. The relationship between cause and effect is more obvious in injuries of the skeleton at the ankle and wrist than in any other part of the body, probably because of their proximity to the part of the body

coming in contact with the ground or injuring object. In these injuries we recognize more clearly the effects of the falls on the palm of the hand and the turning of the foot inward or outward due to the lateral instability of the foot. In no other parts of the body is there the same unity of opinion concerning the mechanism of fractures and dislocations. My whole case has been built up on the hypothesis that hyperabduction is to shoulder injuries what forced dorsal flexion is to wrist injuries and the lateral turns of the foot are to injuries of the ankle. But the influence of hyperabduction is not so obvious. A little reflection, however, will show that no movement at the shoulder is forced as frequently and violently as abduction. Only the muscles and joint ligaments on the axillary side resist, and as the capsule is an integral part of the skeleton it must suffer more than any other soft structure from the forces applied to the skeleton. It has been my contention that in falling, if conscious, a person practically never strikes on his shoulder, and I regard it as very important that Codman, who has been a close student of shoulder injuries, agrees with this contention. I believe that in falling one practically always puts out his hand to break the force of the fall and that the effect at the shoulder is to carry the arm into abduction. The only pathologic effect of hyperabduction at the shoulder that is generally recognized is the anterior dislocation, and even in this condition we have not appreciated its full importance. In my opinion, it is the key to the solution of the obscurity in most shoulder injuries.

I wish to suggest here how it may explain other injuries to the skeleton than at the shoulder-joint. The lateral turns of the foot produce sprains and sprain fractures, Pott's fractures, lateral dislocations of the subastragaloid joint and even of the ankle-joint, and probably other injuries to the skeleton, also. At the shoulder, what do we know, for instance, of the mechanism of fractures and dislocations of the clavicle, or fractures of the surgical neck of the humerus? We know practically nothing, so that a plausible suggestion

should be worth while. Without movement of the scapula, abduction is arrested at or a little above the horizontal by tension on the axillary portion of the capsule which turns the scapula on further abduction (Fig. 1). When the normal limit of abduction is passed, some part of the skeleton gives way. In adults, in the great majority of cases, this is probably the shoulder-capsule, which includes all the ligaments of the shoulder-joint; but why should not other parts of the skeleton break, here, as at the ankle? My cadaver studies show that the first effect of hyper-

abduction at the shoulder-joint is to tear the axillary portion of the capsule. Then the outer surface of the humerus just below the tuberosities strikes the edge of the acromion, when further abduction pries the humeral head out of its socket below and anteriorly (that is, into the axilla), the humerus sliding on the acromion at their point of contact (Fig. 2). But the dislocation is the end-result of hyperabduction and requires an extensive tear of the capsule. Between the force necessary to produce this severe result and

Figs. 8 and 9.—Same as Figures 5 and 6, with humerus in about same plane as clavicle and acromion, showing same displacement of outer fragment as in Figures 4 and 7.

that which the capsule can withstand without tearing, there will be many grades applied, producing lesser tears or sprains of the shoulder-joint. There are, in all probability, many cases in which dislocations are spontaneously reduced as the arm falls to the side of the body. Most traumatic stiff and painful shoulders are probably due to lacerations of the axillary portion of the capsule produced by hyperabduction. But with the tearing of the capsule, or without it, a neighboring part of the skeleton may give way.

It is a significant fact that fracture of the surgical neck of the humerus is not infrequently associated with an anterior dislocation of the shoulder. It is more than likely, in such cases, that both lesions are due to the same mechanism, and it is generally agreed that the dislocation is due to hyperabduction. The limitation of movement in the shoulder-joint, fre-

Fig. 10.—Upward dislocation of inner end of clavicle from hyperabduction. The relation of the sternum to the clavicle prevents the downward displacement of the latter.

quently observed and often severe after fracture of the surgical neck without dislocation, could be explained by a simultaneous tear of the capsule, with or without a simultaneously reduced dislocation. The fracture would represent the breaking of the lever, the humerus, at the fulcrum, the acromion (Fig. 1). Mencke¹ has recently called attention to the frequency of fractures of the acromion, which may be explained as the giving way of the fulcrum itself. I shall call

attention, briefly, to other fractures of the fulcrum, later. Mencke found that in some cases the fracture of the acromion was associated with anterior dislocation of the shoulder, which in these cases, at least, is strong evidence that the fractures were due to hyperabduction. Fractures of the greater tuberosity of the humerus are well known to be frequently associated with anterior luxations of the shoulder. I have obtained about ten or twelve typical fractures of the greater tuberosity simply by producing anterior dislocations of the shoulder in the cadaver by hyperabduction. In each instance the capsule tore from its humeral attachment, the continuing abduction tearing the capsule progressively upward to the greater tuberosity which was detached, the varying-sized fragment maintaining its attachment to the corresponding portion of the capsule (Fig. 3) and the overlying rotators. I have operated in several cases and have also had several cadaver dislocations in which the capsule tearing from the glenoid margin carried

with it a fragment of the glenoid. These fractures, therefore, seem to depend on the manner in which the capsule tears from hyperabduction.

The fulcrum, in the leverage mechanism of hyperabduction, is the acromion. But the acromion is attached to the rest of the skeleton by the clavicle, which, therefore, becomes an important part of the fulcrum. This may break at any point, but is more liable to do so at some points than at others. Of the two clavicular joints, the outer gives way much more frequently than the inner, while the clavicle breaks most frequently about its middle where it is thinner and least protected by muscles and ligaments. In his fractures of the acromion, Mencke included cases in which a small fragment was detached from its articulating surface with the outer end of the clavicle. I have seen one case of this kind and several others in which the Roentgen ray failed to show such a fracture, but in which the pain following an injury to the shoulder was sharply localized to this joint. I have had two cases in which an upward dislocation of the outer end of the clavicle (by far the most frequent variety) was associated with an anterior dislocation of the shoulder which indicates that both resulted from hyperabduction. The line of this joint is slightly oblique from above downward and inward, the obliquity varying

Fig. 11.—Left shoulder injured three years ago. Severe paralysis appeared on following day. Total paralysis of hand four weeks later when shoulder ankylosis was broken up under ether. Returned to work in six weeks with limb weak, especially hand. Normal power and motion in one year. Picture taken one week ago showing patient supporting 40-pound dumb-bell with left arm, which is about as strong as right.

1. Mencke: Ann. Surg., 1914, lix, 233.

in different cases. The effect of the leverage mechanism at this joint is to crowd the acromion inward against the outer end of the clavicle, and if the force is strong enough, to drive the acromion under the clavicle because of the favoring obliquity of the joint and the tendency of the lever to turn the outer end of the acromion upward and the inner end downward (Fig. 4). The force expended at this joint may be sufficient only to cause a painful joint by the strain on or tearing of the ligaments, the contusion from crowding the bones together, or the fragmentation of the apposed articulating surfaces.†

If we regard these four conditions as fractures of the skeleton with overlapping of the fragments, we shall find that the typical deformity is the same in all. In the anterior dislocation of the shoulder (Fig. 5) and typical fracture of the surgical neck of the humerus (Fig. 6), the lower fragment is displaced upward, inward and forward, while in the fracture of the clavicle (Fig. 7) and dislocation of its outer end (Fig. 4), the proximal fragment is displaced downward, inward and forward. The difference here is only apparent, for if the humerus is abducted until it is in the same plane as the clavicle and acromion, then the upward displacement of the humerus in the fracture of the surgical neck and anterior luxation of the shoulder-joint becomes a downward displacement (Figs. 8 and 9) as

Fig. 12.—Showing relation of branches of brachial plexus to torn axillary portion of shoulder capsule. Hemorrhage from this and other injured tissues with synovial fluid from opened joint extravasates around and into the nerves and with the resulting inflammatory exudate produces a palsy of the limb of varying grade and distribution. The torn and relaxed capsule is shortened by the cicatricial healing.

in the fracture and luxation of the clavicle. This similarity in the usual deformity in all of these conditions suggests strongly a common mechanism, hyperabduction, which we agree is responsible for one of them, the anterior dislocation of the shoulder. The well-known greater frequency of fractures of the clavicle in children and dislocations of the shoulder in adults could be explained by a relative difference in strength of these two portions of the skeleton at these two periods in life. The great infrequency of dislocations of the inner end of the clavicle and the usual upward displacement of the proximal fragment in this fracture of the skeleton are readily explained by the conformation of the joint (Fig.

10), which absolutely prevents a downward displacement of the proximal bone or fragment as in the other fractures of the fulcrum. It tends to neutralize the effect of the force and thus to diminish the number of dislocations. The leverage mechanism might crowd the inner end of the clavicle upward in rare cases, but it cannot force it downward as it does in the other fractures of the skeleton referred to. I have offered, here, these few brief suggestions concerning other breaks in the skeleton than at the shoulder-joint to show that, probably, we have overlooked the possibilities of hyperabduction in the shoulder region. My particular interest is in its effect on the shoulder-joint.

STIFF AND PAINFUL SHOULDERS²

According to my conception, the very frequent stiff and painful shoulders, which have been so obscure and the subject of so much discussion, represent the same condition at the shoulder as follows sprains and dislocation in other joints. The characteristic limitation of abduction and external rotation results from immobilization of the arm in the "sling" position, that is, in adduction and internal rotation. A varying grade of palsy is always present in the early stages and is due to the inclusion of some or all of the branches of the

Fig. 13.—Left shoulder operated on for recurrent dislocations, Dec. 29, 1909. Same shoulder dislocated in wrestling, Nov. 25, 1912. Patient has again taken up wrestling. This picture taken a few weeks ago. Obviously more severe strain in getting into than maintaining this position.

Fig. 14.—Patient operated on six and a half years ago for recurrent dislocations of right shoulder. No recurrence of dislocation since. Patient supporting whole weight by hanging from right hand.

Fig. 15.—Same patient as in Figure 14 supporting his whole weight by standing on right hand.

brachial plexus in the consequent axillary inflammation. This is usually mild and soon disappears with the return of normal motion to the shoulder joint. In some cases it is severe, affects most the muscles of the shoulder region, but in rare cases it involves most the muscles of the forearm and hand (Fig. 11). The therapeutic indication is to restore normal motion by exercises to stretch or forcible manipulations under ether to tear the contracted axillary tissues, especially the capsule (Fig. 12).

RECURRENT DISLOCATIONS OF THE SHOULDER³

If after the reduction of a dislocation of the shoulder, the arm is not kept at the side and is soon carried forcibly into abduction, particularly if external rotation is added, the humeral head is easily pried out of the socket again because the capsule has not had time to heal. Its torn edges are again forced apart and

† Recently, Sievers, in the Trendelenburg Festschrift of the Deutsch. Zeitschrift für Chirurgie, cxxix, 583, presented an extensive study, showing that injuries of this joint are frequent.

the repetition of this accident will leave them permanently separated by the width of the gap necessary for a dislocation, the gap becoming filled in by new cicatricial capsule, much as the gap in a divided Achilles tendon is filled in. The lengthened axillary portion of capsule will not now contract and a recur-

This was a complete failure. The other four (non-epileptics) were successful later, because the condition produced by the dislocation, with the arm kept at the side four or five weeks, induces a cicatricial contraction of the axillary portion of the capsule just as it does after a recent dislocation. After operation the capsule must tear before a dislocation can take place, so that if advantage is taken of this fact the capsule may become as strong or stronger than before the dislocation. For this reason the patients are encouraged to make the fullest use of the arm and are told that the condition necessary for a recurrent dislocation will not return (Fig. 13). In this way the possibilities of the repaired shoulder are developed and the usual persistent fear of a recurrence is done away with (Figs. 14 and 15).

BRACHIAL PALSY FROM INJURY TO THE SHOULDER REGION⁷

The obvious cause of a brachial palsy following an injury to the shoulder region is an injury to the nerves supplying the part paralyzed. The prevailing view is that they are due to a more or less complete rupture of one or more roots of the brachial plexus. I have tried to show that most of them, in adults, are due to the inclusion of the branches of the plexus in the axillary inflammation consequent on a laceration of the axillary portion of the shoulder-capsule (Fig. 12). I wish to state moreover that nearly all the cases which have come under my observation have been associated with an ankylosis of the shoulder-joint and a characteristic limitation of abduction and exter-

rent dislocation is established. Shortening by overlapping or folding of the lengthened capsule is indicated.

Five years ago I reported the first case in which the operation was done through the axilla and was the first to exclude all other causes than the lengthened axillary portion of capsule. I have now done the operation on twenty-two shoulders. Telford⁴ did it in two cases and recommended it highly. Stimson⁵ spoke of it as the ideal operation, and, recently, Schultze⁶ excluded all other causes than the relaxation of the axillary portion of the capsule and favored the axillary operation, although it was not done in any of his cases. A 4- or 5-inch incision is made posterior to the axillary vessels, no muscles are divided, no sutures except those in the skin remain, those used to overlap the capsule being withdrawn when the arm is in the Velpeau position so that the overlapping cannot afterward be disturbed, and ligatures are rarely necessary. The only infection was due to a tense capsule suture that grasped too much tissue and was tied too tightly, causing necrosis. This was in the third case operated on and it cannot occur again because no capsule sutures are employed.

In five cases a dislocation occurred after operation from severe violence with the arm in abduction and external rotation, and in one case after two operations in an epileptic with powerful convulsions and a large defect in the humeral head.

Fig. 17.—Obstetric palsy with posterior subluxation incompletely reduced by operation at 7½ years of age. No paralysis now. Range of movement and power very similar to that in case of old unreduced dislocation of shoulder in adult (Fig. 21).

Fig. 16.—Typical position in obstetric palsy. Mother said to have recognized dislocation of shoulder one week after birth.

Figs. 18 and 19.—Complete palsy of right arm at birth. Then ascribed to rupture of the brachial plexus. Right limb as strong and as large as left now. Slight limitation of abduction and external rotation due to mild posterior subluxation of shoulder.

nal rotation, the disappearance of which was followed by a return of the normal power. The key to the solution of the problem is the anterior dislocation of the

shoulder in which we know an extensive laceration of the capsule occurs. The brachial palsy in the newborn resulting from injury to the shoulder region during delivery is generally agreed to be of the same nature and due to the same cause as that in the adult, an injury to the brachial plexus. My experience and

study lead me to believe that most of them are the results of injuries of the shoulder-joint as in adults. That birth-palsies are due to injuries of the skeleton in the shoulder region and not to injuries of the brachial plexus is not a new suggestion. Küstner,⁸ in 1889, argued at length to show that they were due to separations of the upper epiphysis of the humerus and that those with deformity were due to displacement of the diaphyseal fragment backward or forward. The evidence is rapidly growing which will show that these displacements are almost always due to posterior subluxations of the shoulder-joint. Küstner suggested that mild obstetric palsies in which the paral-

ysis disappeared in a few days might have been due to blood extravasations the pressure of which paralyzed the nerves. Von Bramann⁹ quotes Vogt to the effect that in congenital dislocations of the shoulder there was a paralysis due to the displacement in the shoulder-joint. Von Bramann believes that the muscles suffer from their inactivity without being paralyzed.

According to my conception, the adult and the birth cases are similar because they are both due to injuries of the shoulder-joint, the basic lesion in both being that of a dislocation of the shoulder. In the adult, when there is no dislocation, complete recovery ultimately results in the great majority of cases. This seems to be true of the birth palsies. When the dislocation persists in the adult, there remains a permanent crippling of the arm and a considerable palsy which in the early stages was much more severe. The condition is very similar in the child when there is a dislocation present (compare Figures 17 and 21). The more delicate muscles and nerves in the child will account for a more severe palsy in all stages, but the improvement in them is also very marked as the years go by. The treatment based on this conception gives far better results than that based on a supposed rupture of the brachial plexus. F. Lange,¹⁰ who has adopted the theory of a shoulder-joint origin, says that the day for the "let alone" treatment of obstetric palsy has passed by. The great need at the present time is to recognize the mild grades of posterior subluxation in these cases. It will often take careful

examination to determine the absence of the normal rounded prominence of the humerus in front of the acromion and the slight prominence of the head behind the acromion where there should be a slight depression.

OLD UNREDUCED DISLOCATIONS OF THE SHOULDER¹¹

From cadaver and clinical study it was assumed that the chief obstacle to reduction was in the cicatricial changes in the torn and now abnormally arranged capsule, some portions healing short and resisting the reduction. As the head left the socket with the arm in abduction, the best method of reduction should be to drag the head back into the socket with the arm in the same position. This would be applying to the shoulder the Allis principle for the reduction of dislocations of the hip. The Kocher method is the application to the shoulder of the Bigelow principle for the reduction of dislocations of the hip. By fixing the scapula firmly and confining the traction to the humerus, the force applied will be confined to the structure holding the scapula and humerus together, that is, the cicatricially altered capsule which must be torn before the head can be moved from its dislocated position. Very severe traction was made in nine cases (see summary), but caused no troublesome symptoms in any. The same method proved successful in recent dislocations of the shoulder.

BRACHIAL PARALYSIS WITH FLAIL SHOULDER-JOINT¹²

Brachial paralysis without the flail shoulder is much more common than with the flail shoulder. The injury to the brachial plexus is assumed to be responsible for both, but we have no explanation for this very important difference in the results of this lesion. The cases without flail shoulder practically always recover with the return of normal motion to the shoulder-joint. I believe there was not a case on record of recovery of the flail shoulder type until I reported two such recoveries three years ago (Fig. 22). These recoveries followed merely the operative removal of the flail shoulder within eight weeks after the causal injury and the restoration of the normal motion to this joint (see summary). My conception of the etiology of these cases is that they are due to the same mechanism as those without flail shoulder, except that the attachments of the capsule and rotator muscles are so torn that the humerus falls away from the socket until it is supported by the surrounding uniform muscles and other tissues (Fig. 3).

Fig. 20.—Obstetric palsy at birth without dislocation of shoulder. Now has evidence of old injury at elbow and very slight limitation of abduction and external rotation in affected (right) shoulder. No evidence of paralysis now. Uses right arm freely and powerfully as left.

Fig. 21.—Dislocation of right shoulder three years ago. Still unreduced. Movement and power much improved by exercises during past year, favored, probably, by wearing away of dislocated bones where they are in contact (see Fig. 5).

SUMMARY OF CASES AND RESULTS OF TREATMENT

The treatment in each condition has been based on new conceptions as to etiology. This is less true of recurrent dislocations than of any of the other conditions, the contraction of the capsule having been done occasionally for about thirty years. In January of this year, I published the results of this operation in eighteen shoulders. In April, Schultze reported the late results in thirteen shoulders operated on in Bier's clinic since 1908. I have now operated on twenty-two shoulders. These are the only two reported groups of cases in which a satisfactory comparison of results can be made.

SCHULTZE'S CASES

Since 1908 capsulorrhaphy done in.....	16 shoulders
Late results investigated in.....	13 shoulders
Recurrence of dislocation (regarded as failures) in	7 shoulders
No recurrence in.....	6 shoulders
Shortest interval since operation, 1¼ years.	

AUTHOR'S CASES

Since Jan. 18, 1908, capsulorrhaphy in.....	22 shoulders
Recurrence of dislocation in	5 shoulders
No recurrence	17 shoulders
(Excision later in one of these.)	

Of the 5 cases with recurrence after operation, 4 were later made successful without operation and 1 was a failure after two operations. Operations in epileptics... 7 cases Successful (no recurrences) 6 cases Failure in 1 case

Old Unreduced Dislocations in Adults

Non-operative reduction successful:
After 8 months; 4 months; 8 weeks (with fracture of shaft of humerus); 25 days, and 16 days.
Non-operative reduction failed after 3 months; excision; fatal from hemorrhage.
Reduction accomplished but not maintained:
After 2 years; 4 years; and 5 years (excision with good results).
Very marked improvement in motion and power from exercises in the two cases not excised.

Obstetric Palsy

Number of cases.....	13
Without posterior subluxation of shoulder	4
Perfect recovery of power and motion	2

Very slight and negligible limitation of motion at shoulder and old injury at elbow.....	1
Six months old and excellent promise of complete recovery of power and motion.....	1
With posterior subluxation of shoulder	9
Incomplete reduction (obstructing portion of acromion not recognized and removed).....	2
Complete reduction.....	2
Almost complete reduction.....	1
Mild subluxation not reduced.....	1

Excellent results in these six cases, varying largely with the degree of motion attained and, therefore, with the time since treatment began and completeness of reduction.	
Operative reduction of anterior luxation of head of radius; recurrence.....	1
No attempt at reduction of shoulder luxation and indifferent treatment.....	2

Brachial Paralysis with Flail Shoulder

Operative Removal of Relaxation:

Adults:

Complete recovery of motion and power.....	2
Left country early with stiffness of shoulder, but recovery of paralysis.....	1
Comminuted fracture of middle of humerus with improvement of paralysis, but non-union.....	1
Stiffness of all joints but recovery of paralysis.....	2

Children:

Encouraging improvement of paralysis, but far from satisfactory	4
---	---

Miscellaneous Operations

Exposure of subacromial bursa	3
Exposure of greater tuberosity	4
Suppurative arthritis (axillary drainage).....	1
Second capsulorrhaphy for recurrent dislocation.....	1
Excision after capsulorrhaphy for recurrent dislocation..	1
Total number of operations on shoulder.....	49

I wish to acknowledge my indebtedness to the artist, Mr. Erwin F. Faber, of the University of Pennsylvania, for his assistance in the preparation of these diagrams.

2005 Chestnut Street.

ABSTRACT OF DISCUSSION

DR. ALFRED C. WOOD, Philadelphia: As opportunity is rarely afforded to examine a joint by dissection soon after an injury, our knowledge of the joint lesions due to traumatism is very imperfect.

We will be obliged, I believe, to change our views on some of the points that have hitherto been generally accepted concerning these lesions. The suggestion that the several fractures in the neighborhood of the shoulder-joint result from a common mechanism, is ingenious, and, I believe, is sound.

A prolonged or permanent disability of the shoulder after dislocation in certain cases is well known. In addition, however, a large number of cases are met in which a shoulder injury that appears to be relatively trivial is followed by quite as much impairment. These patients have been treated for chronic rheumatism, chronic arthritis, peri-arthritis, neuritis, etc. We are all familiar with the long and tedious course of these cases when subjected to the ordinary methods of treatment. The explanation just given offers a perfectly satisfactory theory which hitherto has been lacking. The capsule of the shoulder-joint being long enough to permit of a wide range of motion, some portion of it in most positions of the extremity, is relaxed or even thrown into folds. When the elbow is at the side of the chest, the upper surface of the capsule is tense and the axillary portion is lax. If there has been a rupture of this portion of the capsule and the arm is allowed to remain at the side during healing, the tear unites with the capsule more or less plicated and hence the latter becomes unduly shortened. In addition, the circumflex nerve may become involved in the scar. From one or both causes, but chiefly from the shortened capsule, there is greatly restricted motion at the shoulder-joint which it is sometimes difficult to restore to the normal range. To prevent the occurrence of this disability in cases of dislocation or when injury to the capsule is suspected, I have recently been advising that the humerus be kept in a position of partial abduction so that the axillary part of the capsule will be straightened out and smooth instead of lying in folds. If properly carried out I believe this will overcome the restriction of abduction so frequently seen. On the other hand, the abduction must not be sufficient to permit the head of the humerus to drop from the glenoid surface or to cause separation of the capsular tear.

DR. T. TURNER THOMAS, Philadelphia: I wish to confirm and, if possible, to emphasize Dr. Wood's statement.

In two cases of anterior dislocation of the shoulder associated with fracture of the surgical neck of the humerus,

Fig. 22.—Brachial paralysis of left side with flail shoulder joint following shoulder injury five years ago. Relaxation of upper and posterior portion of capsule and overlying rotator muscles overcome by operation, eight weeks after accident. Power and motion of limb practically normal about four months later and have remained so since. Some permanent atrophy of infrascapular muscles from operative shortening.

I observed his operations and I regard his results in these cases as important. We all know how difficult the reduction of the dislocation may be under such circumstances, with or without operation. In both cases he attempted reduction before operation without success and after freely exposing the head with the same result at this stage in both cases, he divided freely the tense, torn margin of the capsule which had been separated from the humeral attachment and had passed over and behind the head under much tension. To reenter the socket the head had to pass under that tense capsule edge, which was almost if not quite an insuperable obstruction. The free division of this portion of the capsule solved the difficulty and in both cases was followed by easy reduction. The principle is the same as that employed in the reduction by operation of those posterior dislocations at the metacarpophalangeal joint of the thumb which are irreducible without operation. Dr. Wood has shown that such devices as the McBurney hook for pulling the head into the socket, and excision of the head, are unnecessary in these troublesome cases.

A SUBSTITUTE FOR POTASSIUM PERMANGANATE TO LIBERATE FORMALDEHYD GAS FROM A WATER SOLUTION

SAMUEL G. DIXON, M.D., LL.D.

Commissioner of Health, Commonwealth of Pennsylvania

HARRISBURG, PA.

Almost immediately after the declaration of war by Germany I requested the department's chemist, Mr. Charles Lawall, to proceed at once to find a substitute for potassium permanganate that would liberate formaldehyd gas from a water solution for the purpose of disinfecting.

In the literature no mention of any other specific substance was found except in an English patent application (4885, J. S. C. I., 1908, page 915), where a combination of sodium bisulphite and formaldehyd solution was acted on by potassium permanganate or other peracid salt and the dry fumigation formula:

Formaldehyd, 37 per cent. solution..... 2 parts
Saturated alum sulphate solution..... 1 part

Eight ounces of this solution are used to 1 pound of lime to 1,000 cubic feet.

Dr. George Rosengarten suggested sodium dichromate as a cheap oxidizing agent, and hydrochloric acid to increase its energy. Lawall found on experimenting that sodium dichromate was more energetic and satisfactory in the presence of sulphuric acid.

Numerous experiments, confirmed by calculations on the relative oxidizing power of potassium permanganate and sodium dichromate, and also working out the optimum proportion of sulphuric acid, led to the conclusion that the following proportion gave the best results, which are in every way comparable to those with potassium permanganate:

Sodium dichromate 10 ounces avoirdupois.
Saturated solution of formaldehyd gas 1 pint.
Sulphuric acid, commercial, 1½ fluidounces.

The sulphuric acid and formaldehyd gas form a stable solution. This after it cools should be poured over the crystals of sodium dichromate spread out in a thin layer over the bottom of a vessel having ten times the capacity of the volume of ingredients used.

It was found that the process was more rapid than with potassium permanganate. This would necessi-

tate the health officer's withdrawing promptly from a room in which the process had been started.

Lawall, when working on a small scale, found in every case a corrosive residue. Much to his surprise the residue in ten minutes was dry and pulverulent, and a galvanized bucket which had been used showed very little effect of the reaction after washing out with soap and water.

He made a quantitative determination by both the permanganate and dichromate methods to determine the amount of volatile material given off and found that in each case it approximated 8 ounces avoirdupois (or about half the weight of the formaldehyd solution taken).

As formaldehyd solution contains between 35 and 40 per cent. of gaseous HCOH and as the residue in each case was found to be dry and particularly devoid of odor after two hours' standing, Lawall concluded that the two methods are equally effective from the quantitative standpoint.

Formaldehyd solution and commercial sulphuric acid may be kept in stock and shipped in the mixed form (10 parts of formaldehyd solution and 1 part sulphuric acid, both by volume). Lawall found the solution would be perfectly stable.

The solution would have to be handled with more care than the plain formaldehyd on account of the acid making it slightly corrosive.

Extensive Scalp and Brain Wound.—J. P., aged 28, American, while working in a planing mill, crawled under the table of a rip-saw to adjust a set-screw. Apparently forgetting the location of the saw, he raised his head, striking the saw which was making 2,500 revolutions per minute. The saw literally split his head open from well down on the forehead diagonally across the head, a distance of 8 inches, cutting through the scalp, bone, superior longitudinal sinus, membranes of the brain, and considerable brain tissue. The patient walked about one hundred yards when he collapsed. The hemorrhage was terrific. The width of the cut was one-fourth inch. I saw the patient about four or five minutes after the injury, and controlled the hemorrhage temporarily by a sterile gauze pack extending well down through the bone. The patient was then removed to a quiet room at a hotel, no hospital being available. With the assistance of Dr. J. F. Abel, I shaved the scalp, washed the head, removed the one large piece of gauze, and replaced four pieces of iodoform gauze packing, which controlled the hemorrhage and drained the wound. The scalp wound was then closed between the gauze packs with sutures. The patient was kept quiet for four days when he was removed to the Mission Hospital, Asheville, N. C., and treated by Dr. M. H. Fletcher, who removed the gauze packs and gave the wound the necessary attention. Considerable brain tissue oozed from the wound while at the hospital. The patient made an uninterrupted recovery and left the hospital the fifth week. He suffered very little during the whole time of confinement, and showed no signs of paralysis or any bad after-effects. He returned to work the eighth week after the injury.

Patient with extensive scalp injury after recovery.

SAM L. STRINGFIELD, M.D., Sunburst, N. C.

FOREIGN BODIES IN STOMACH

REPORT OF AN UNUSUAL CASE

J. LEWIS DAY, M.D.

Assistant Physician, Oklahoma Hospital for the Insane

NORMAN, OKLA.

Many cases of swallowing of foreign bodies, especially among the insane, have been reported, but I have failed to find a case in which so large a number of articles were found in one stomach.¹

History.—The patient, M. M., colored man, aged 27, was admitted to the hospital July 9, 1911, for manic depressive insanity. He was born in Mississippi, was illiterate, and had spent one year in Tennessee State Hospital. The physical condition was good.

The patient's history in our hospital was uneventful. He was noted for his robust physique and irritable temper, was violent and frequently engaged in fights with other patients and his attendants. At no time was he discovered picking up nails or glass, or swallowing these substances; consequently he must have used a great deal of cunning in accomplishing his purpose. He had never been reported sick until

Foreign bodies found in stomach at necropsy of insane patient.

June 12, 1914, when he complained of dyspnea and abdominal pain. Physical examination at this time revealed marked edema of lower extremities, and ascites. The heart and lungs were normal, urinalysis negative, temperature 98.4, pulse 80, respiration 18. Subjective symptoms were indefinite pain and tenderness in abdomen. After a few days of rest in bed with appropriate diet and good elimination, all symptoms improved, but a moderate amount of ascites remained; there was no indication of intestinal obstruction. There was some dyspnea, but the chief complaint was pain in the abdomen. On account of the patient's mental state it was impossible to obtain reliable subjective symptoms.

June 18, 8 a. m., the temperature was 98, pulse 100, respiration 20. Patient had lost in weight and strength and looked sick but sat up in bed, drank his milk with relish at noon, and asked for meat. He died at 4:15 p. m.

Necropsy Report.—Mulatto, medium height, well nourished, with moderate abdominal distention. Lungs were adherent practically over entire surface to thoracic walls and pericardium. There were no tuberculous lesions. There was extensive anthracosis. Heart was of normal size, with no valvular lesion, and no sclerosis of aorta or other arteries.

About 2 liters of straw-colored ascitic fluid were taken from abdominal cavity. The intestines were not markedly abnormal; some adhesions were found about the appendix. The omentum was diminished in size, congested and adherent to stomach, was displaced backward and below the stomach, almost in relation with the posterior abdominal wall. The liver was small, surface smooth, gall-bladder filled, but normal; kidneys normal in size and consistency. Pyloric end of the stomach was displaced upward, backward and to the right, lying under the right lobe of the liver. Cardiac end normally placed, distended with gas. Stomach was removed and 236 separate articles weighing, net, 1 pound 9 ounces were removed (see illustration). The walls of the cardiac end of the stomach were not abnormal. Pyloric end was very much thickened and thickly studded with numerous villiform overgrowths. The foreign bodies were practically all collected in the pyloric end, many being embedded in the stomach walls. Pylorus was patent. No undigested food remained in stomach. Esophagus was not abnormal. Stomach contents and walls of pyloric end were blackened, apparently from action of iron. There was no evidence of recent or remote perforations of stomach walls, unless the abnormally adherent omentum might indicate former perforation.

It was evident that many articles had been in the stomach for a matter of perhaps years. Some of the pieces were never known at our hospital; hence the patient must have brought them with him nearly three years before. The fact that such things could remain in the stomach for so long a time and yet patient go about his duties, eat well, remain well nourished and do, whenever called on, heavy manual labor, should be of interest. As short a time as two weeks before his death he carried 100-pound sacks of flour from trucks to the store-room. We are inclined to think that pins, nails or other large objects and especially glass, when swallowed, may mean death or at least alarming symptoms; but this case shows that an abundance of hardware may be ingested and yet the patient live for months and years, with no apparent distress.

ADDENDUM

[A number of cases are on record in which a considerable number of articles were found in the stomach which had carried them, in some cases for years; without showing signs of serious injury. Perhaps the most remarkable are those in which pieces of broken glass with sharp angles are tolerated by the gastric mucous membrane without perforation resulting. Meisenbach¹ extracted a large number of articles including an ounce of broken glass (electric light globe) from the stomach of a professional glass-eater who styled himself "the Human Ostrich." W. S. Halsted² reports a case in which he extracted from the stomach of a professional glass eater 74 gm. of broken glass and 208 articles, consisting of 28 pieces of chain, 99 nails and 81 screws, knives, tacks, pins, etc. G. F. Inch³ reported a similar case. A. H. Vandivert and H. P. Mills⁴ report finding at necropsy of an insane patient, an amount of miscellaneous articles numbering 1,446 and weighing 2,268 gm. There were no signs of trouble with the stomach, digestion being good until a few days before death. These cases show the importance of a Roentgen-ray examination in such obscure conditions. In each instance such an examination would no doubt have revealed the source of the trouble.]

FRACTURE OF THE FEMUR INTO AN ACTIVELY TUBERCULOUS KNEE-JOINT

WITH HEALING OF THE FRACTURE

CHARLES A. PARKER, M.D.
CHICAGO

The following case recently under the care of Dr. Ridlon and myself appears to be of sufficient clinical importance to merit recording:

History.—The patient is a man aged 26, who has suffered more or less continuously from trouble in his right knee since he was 6 years old. It had been pronounced tuberculous. During the last two years he experienced a severe recrudescence of the trouble. In October, 1912, he fell on the knee and a diagnosis of fracture was made by the attending surgeon, and various treatments of the fracture and of the joint were carried out.

He came to our office March 18, 1913, wearing a cast and with a discharging sinus over the inner aspect of the knee. The knee was straight, swollen and had slight motion in flexion. There was more lateral motion and the joint was very sensitive. A roentgenogram was taken and a cast applied.

Figure 1 shows the type and extent of the fracture as well as the amount of destruction in the joint.

It is a typical supracondylar fracture of the femur with a vertical fracture through the external condyle down into the joint, and an oblique fracture extending 2 or 3 inches up into the shaft of the femur.

Whether or not there were more vertical clefts originally present, it is impossible to say from the picture. The picture shows some evidence of callus formation on either side of the femur overlapping the transverse fracture and a large posterior shadow that looks like callus, but without definite outline. The joint surfaces show a typical tuberculous picture. On account of the extreme tenderness of the part no attempt was made to determine the character of the union of the fracture; but the character of the joint and the age

parts through a stab wound in the posterior flap. Healing was prompt and uneventful.

The Specimen.—The soft tissues were removed from the specimen and the bone examined. Incidentally it may be noted that the region back of the joint, that is so definitely defined in the roentgenogram and appears as a deposit of lime-salts, showed nothing abnormal to the naked eye, although it was believed that a slight grating on the knife could be detected on scraping the cut surface. It consisted mostly of the popliteal fat in which there were no doubt calcareous elements, but not arranged so as to form any definite calcareous structure. The callus seen on either side of the femur in the roentgenogram was very slight and soft, but the

union of all the parts of the lower end of the femur was so firm that no movement whatever could be detected in them on testing the strength in our hands; in fact, there was a definite firm bony union with good position and in the presence of an actively tuberculous joint (Fig. 2). A histologic study of the tissue taken from the region of the posterior shadow failed to show any lime deposits or other conditions that might produce such a shadow. An excess of lime-salt may have been present, but not in a form recognizable by histologic methods.

Fig. 2.—Section of lower end of femur in Figure 1, showing union of fragments.

Of course one instance is hardly sufficient on which to base a rule of practice, but it is the best evidence of what has occurred and in so much may influence us as to what may occur again. In other words, a fracture into an actively tuberculous joint can heal in a satisfactory manner, leaving only the original joint trouble for treatment according to the usual methods pursued in such troubles. Possibly another case may not progress so favorably as this case as far as the fracture is concerned, but this case certainly justifies us in expecting the bony union and a final healing of the joint in those cases in which the conservative healing of the joint is ordinarily indicated.

Another fact that should be emphasized in this connection is the presence of a shadow strongly suggestive of callus in a region in which operation demonstrates no callus to be present; or, in other words, what appears to be an insurmountable obstruction to flexion is in reality no obstruction at all.

7 West Madison Street.

Fig. 1.—Roentgenogram showing fracture of the lower end of the femur extending into the actively tuberculous joint.

of the patient, together with his appearance of suffering from chronic sepsis, influenced us to suggest amputation of the thigh as the best solution of the problem. This was agreed on and the thigh was amputated just above the lower third, April 3, 1913. The operation was performed at the Presbyterian Hospital. A large tuberculous abscess was opened when the muscles of the front of the thigh were cut, four or five inches above the joint. Its walls were removed together with considerable sound tissue and the whole surface sponged with tincture of iodine and the wound entirely closed, a small gutta-percha drain extending into the deeper

The Value of a Pleasant Hospital Exterior.—In the description of a hospital a writer in *Country Life* says: "It is sometimes said that it is wrong to expend any money on the outside of a hospital, and that every halfpenny should be devoted to operating-tables and the like. This is surely a prejudiced idea. No building of a public sort should present a repellent front to the passerby; least of all, a hospital, which owes a smiling welcome to those who approach it with some sinking of heart. There are hospitals enough which suggest by their door faces, 'All hope abandon ye who enter here.' We need not be psychologists to recognize that none more than the sick need the subtle aid, not only of a happy environment within, but of the cheering welcome of an exterior that is homelike rather than 'institutional.'"

A CASE OF SPOROTRICHOSIS

L. A. DERMODY, M.D. AND C. McMARTIN, M.D., OMAHA

Mrs. G. G., aged 35, born and residing in Nebraska, with family and past history of no importance, noticed in November, 1913, what she termed a "red welt," pea-sized, oblong and painless, on the dorsolateral surface of the middle finger of the left hand. She can recall no trauma immediately preceding the lesion or at any time previous.

In from four to seven days after the appearance of the "welt," suppuration took place. The pus had no unusual color. One week later the patient noticed a red line extending up the extensor surface of the forearm as far as the elbow. This red line remained one week, gradually faded, and along the exact course it had taken she noticed a number of nodules just beneath the skin, not painful, from the size of a large shot to that of a cherry. These nodules extended about half way up the arm above the elbow, following definitely the course of the superficial lymphatics. There were never more than twelve or thirteen nodules. At this time she consulted her local doctor (about three weeks after the appearance of the initial lesion on the finger). The nodules were gradually growing larger and assuming a purplish color, but were not painful, nor had they suppurated. The physician incised the lesion on the finger, evacuated some pus and applied a moist dressing. Three weeks of this treatment gave no benefit and the patient felt that she was growing worse.

She came to Omaha and on Dec. 26, 1913, the nodules were opened, curetted and cauterized with phenol (carbolic acid)

Sporotrichosis lesions.

followed by alcohol. Temporary improvement took place, but at the end of two months the patient returned home with the areas of infection draining freely. Three months after this she returned with no improvement. No new nodules had developed.

At this time Dr. McMartin saw her and made a diagnosis of sporotrichosis. Cultures from the pus were made. A 2 per cent. glucose-agar showed at the end of five days a pure culture of sporotricha, spores predominating. A bouillon culture at the end of five days exhibited abundant growth, mycelium forms predominating.

April 16, 1914, the patient was anesthetized, and a number of curvilinear incisions made, each one exposing two or three of the nodules. These areas were thoroughly curetted, the skin undermined and the flaps stitched back, exposing the infected fields. One hour each day for three successive days the arm was exposed to the sun's rays. At the end of that time a healthy granulating surface had appeared and the flaps were loosened and sutured in place. The wounds were irrigated daily with 50 per cent. Lugol's solution until almost healed. A daily dressing of Lugol's solution was also applied. Increasing doses of potassium iodid were administered until 60 grains daily were being taken. At the end of six weeks the patient was allowed to return home with the arm entirely healed except for one small area which was rapidly closing.

Her report from the patient since leaving the hospital is that the arm is long since healed and is now perfectly

REPORT OF A CASE OF CEREBRAL HEMORRHAGE

WALTER W. MOTT, M.D., WHITE PLAINS, N. Y.

History.—The patient, a girl aged 3, had always been healthy. At 3 p. m., June 18, while playing, she accidentally stepped backward and fell down several steps, striking her head on a stone sidewalk, the exact manner of falling not being observed. She was able to stand up and walk, and after crying for a short time, she drank some water and went to sleep naturally. She awoke about 4:30 p. m., vomited several times, and appeared dazed. She did not recognize her mother. A slight twitching of her left arm was noticed. I first saw the patient at 5 p. m. The only evidence of external injury was a contusion over the right mastoid region. Pulse was 140, weak but regular. Respirations were irregular and shallow, seven or eight a minute. There was no bleeding from mouth, nose or ears. Pupils were equal, dilated and reacted sluggishly to light. There was no strabismus. By 5:30 p. m. the pulse was weaker and from 170 to 180 a minute. Respirations were even more shallow and irregular. There were convulsive movements of the left arm and leg, the eyes were turned to the right, and the pupils did not react. The lesion was evidently, therefore, an intracranial hemorrhage causing a rapidly increasing cerebral compression, with the focus of the damage over the motor cortex of the right hemisphere. Immediate operation was decided on, and the child was removed to the hospital, a short distance away.

Operation.—The head was shaved and tincture of iodine was applied over the right side. By this time no pulse could be detected at the wrist, the convulsive movements on the left side were almost continuous, and the respirations shallow and sighing. No anesthetic was given. A horseshoe incision was made in the scalp over the right temporal region, and a flap turned down. A trephine opening was then made in the skull over the site of the middle meningeal artery. On removing the button of bone, this artery was found intact. The dura bulged slightly, was blue, and did not pulsate. A small incision in the exposed dura showed oozing from beneath the posterior edge. The trephine opening was enlarged posteriorly with rongeur forceps, and the incision in the dura extended in the same direction. This exposed the site of hemorrhage, a rupture in the ascending frontal branch of the middle cerebral artery. As soon as the subdural pressure was relieved, the twitching of arm and leg ceased, the respirations became regular, and the radial pulse became palpable. The hemorrhage was profuse, and persisted in spite of gentle pressure with gauze. The lesion was given better exposure by a short incision in the dura bisecting the original line, and ligatures of fine plain gut on a round curved needle were passed beneath the artery on either side of the rupture, and tied. These controlled the hemorrhage perfectly. A narrow gauze wick was then carried down to the ligated artery, and the other end brought out through a stab in the flap. The dura was closed about the drain with sutures of fine plain gut, and the scalp and pericranium closed with interrupted sutures of silkworm-gut. The patient was awake and crying when the scalp sutures were inserted.

Postoperative Course.—The patient made an uneventful recovery. The drain and sutures were removed on the fifth day, the wound healing cleanly. She left the hospital on the tenth day, and since then has been perfectly well.

SUMMARY

1. The case was one of rapidly advancing cerebral compression, caused by hemorrhage from a branch of the middle cerebral artery.

2. The distinct "free interval" after the injury, and the later rapid increase in the severity of the symptoms, distinguished the condition from one of cerebral concussion.

3. The injury to the artery was caused by indirect violence, the blow on the head apparently being sustained over the right mastoid region.

4. The convulsive movements on the left side of the body pointed to a lesion involving the motor cortex of the right hemisphere.

New Instruments and Suggestions

A RECORD CARD FOR THE ANESTHETIST

PALUEL J. FLAGG, M.D., NEW YORK

Instructor in Anesthesia, Fordham University Medical School

Those who administer anesthetics sooner or later find it essential to preserve a fairly comprehensive record of each case. This becomes necessary not alone from a scientific point of view, but also for self protection.

Fig. 2.—Reverse of anesthesia record card.

It is frequently inconvenient to gather personal data at the time of the operation. To avoid this embarrassment a record card and a self-addressed, stamped envelope may be left with the nurse, who is usually glad to secure the desired information. The accompanying figures illustrate such a card.

The front of the card (Fig. 1) requires but little comment. Char. of Induction:—Excitement absent, moderate, marked. Anaes. Success:—S.—Point of view of the surgeon; P.—of patient; A.—of Anesthetist.

Heads for data which are absent should be crossed out. On the reverse of the card (Fig. 2) attention may be directed to the following points:

System of Anesthesia: Open, closed, pharyngeal, intra-tracheal, intravenous, rectal, etc.

M. & A.: Morphine and atropine.

Respiration: free, obstructed.

C. Reflex: sharp, dull, absent.

Pupil: normal, contracted, dilated.

Most records are squared off for five-minute pulse-readings. To save space twenty-minute divisions are here used. Five-minute readings may be shown by a dot one-fourth way across the space. These cards may be had from the Surgical Narcosis Supply Co., 13 East Fourteenth Street, New York City.

This record is original only in its arrangement. I wish to express my thanks to Dr. E. M. Hawks and Dr. F. Montgomery for their kind suggestions.

120 Central Park South.

A SELF-RETAINING NEEDLE FOR ADMINISTERING SALVARSAN INTRAVENOUSLY

HENRY EICHEL, M.D., NEW YORK

Those of us who have been giving salvarsan or other closed venous infusions have each developed a preference for a certain needle, which seems to us best fitted for the work in hand. Some of us swear by the straight needle, others are partial to the curved or one of the many modifications of either, and in all cases the esteem in which we hold our special form of needle is the result of the ease with which we seem able to manipulate it.

Not many physicians can give 120 to 200 c.c. of solution by gravity without experiencing a feeling of impatience at having to hold the needle in a fixed position in fear of its slipping out of the vein. And even when employing the

Self-retaining straight needle; A, conical or retention bulb; B, back-stop.

latest syringe method, in coupling and applying pressure to the piston, we are still obsessed with the constant fear of dislocating the needle point from the lumen of the vein and getting an infiltration into the adjacent tissues. This uncertainty and its consequent complications can be obviated by the use of a self-retaining needle. The object of this paper is to describe the principle on which any of the existing needles may be modified and made self-retaining.

DESCRIPTION OF NEEDLE

On an ordinary needle about one-quarter to five-sixteenths of an inch from the base of the cutting edge is a conical bulb beginning flush with the sides of the needle, becoming larger gradually till its diameter is about one and one-half times that of the needle and its length is one-eighth of an inch. This might be called the "retention-bulb" (A in illustration). A larger globular-shaped bulb, about four times the needle's diameter is placed about one-eighth of an inch distant toward the coupling end. The shape of this "back stop" is of little importance (B in illustration).

My own preference is for the straight needle, and I shall therefore describe my method of operation with this improved needle. I puncture the skin and enter the vein, pushing the needle in as far as the "retention bulb," then make a half turn of the needle on its long axis and push to bury the bulb. The bulb becomes firmly fixed in the skin and the needle becomes stationary and practically immovable. This method of fixing the needle may be compared to the venous infusion cannula in which the dilatation is tied within the vein. Here, however, the skin being elastic permits the entrance of the retention-bulb, which is firmly grasped, but does not enter the vein.

I prefer the straight needle because I like to feel that the possibility of puncturing the posterior wall of the vein is at a minimum, and turning the needle, which you can do only with a straight one, accomplishes this end. When the needle point is presenting in the vein, by turning it, the point, being eccentric, is shifted from the line of punc-

ture and puts the cutting edge of the needle parallel to the vein's posterior wall, thus lessening the possibility of passing beyond the venous wall when the retention bulb is pushed under the skin.

CONCLUSIONS

This self-retaining principle, therefore, has the following advantages:

1. It may be applied to any needle.
2. It minimizes the nervous tension on the part of the operator due to the necessity of holding a needle immovable in one position for a tediously long time.
3. The needle cannot be dislocated while it is being coupled to the syringe.
4. Pressure applied to the piston will not dislodge the needle-point.
5. By freeing the hand that would ordinarily be fixed in holding the needle, one may even dispense with the services of an assistant.

54 West One Hundred and Nineteenth Street.

A HANDY MOUTH-FINGER

EDWARD M. MIKKELSEN, M.D., Winnetka, Ill.

It is always difficult, in examining or removing foreign bodies from an eye, to hold the lids apart, focus the condenser, and manipulate a spud or other instrument, all with the fingers of two hands. This led me to devise the little instrument shown in the accompanying illustration.

A handy mouth-finger.

To operate, place shank *E* of condenser under spring clip *D* of mouth-finger, swinging condenser either to right or left, depending on which eye is most convenient for work intended.

Place mouth-piece *F* of instrument between lips and under tongue, without applying teeth to it. The condenser should have a focus of about $2\frac{1}{2}$ inches, which is about 12 or 14 diopters. This gives a working distance between the eye and that of the patient of about 5 to 6 inches. Focus and distance takes care of itself automatically after one becomes accustomed to the instrument, leaving both hands free to do what is necessary.

The instrument is made of aluminum, which leaves no metallic taste in the mouth. The spring clip is made of German silver and the rivets of brass, all non-corrodable on boiling or washing. The instrument is light, fits the vest pocket without bulging, and is a companion piece to the condenser.

A SELF-RECORDING DEVICE FOR TESTING THE COLOR SENSE

J. ELLIS JENNINGS, M.D., St. Louis

For many years the Holmgren colored worsteds have been used by the railways and marine service of the United States and most foreign countries to test the color sense of their employees. When properly used, according to directions, this test has proved to be practicable and reliable. The most serious objections to it are:

1. The worsteds become soiled by constant handling so that the more delicate shades can hardly be distinguished one from the other.

2. The method of recording the skeins selected by the candidate is crude, laborious and liable to lead to error.

In order to overcome these objections I have constructed a test in which the worsteds are not handled and the candidate makes a permanent record of his own color sense. It consists of a square box divided into an upper and a lower half, each half having a lid—virtually two shallow boxes with bottoms joined together. The upper side of the box is marked "Test No. 1 Green," and contains a color board made up of all the different colors, shades and tints likely to be mistaken by the color-blind for green. The lower side of the box is marked "Test No. 2 Rose," and contains a color board made up of all the different colors likely to be mistaken by the color-blind for rose. The color boards, like the box, are absolutely square and each contains sixty-four patches of worsteds of various colors and shades, making a total of 128 colors used in the test.

In each patch of colored worsted is a circular opening in the color board which is for the purpose of registering the particular patch of color chosen by the candidate. This he does by inserting a pointed pencil of wood or metal through the opening and punching a hole in the record sheet which had previously been placed beneath the color board. The position of the patches of color and the circular openings have been arranged in an absolutely symmetrical design, so

Jennings' self-recording color-test.

that when the box is turned in any one of four positions the same appearance is presented and it is impossible to say which is top or which is bottom. The openings of the color boards are so arranged that the records of both the green and rose tests are made on a single sheet.

METHOD OF MAKING THE TEST

The cover marked No. 1 is removed, the color board lifted out, a record blank inserted and the color board replaced. Care must be taken to see that the mark "top" in the box, "top" on the back of the color board and the top of the record blank all correspond. The box is now turned around several times until all sense of direction is lost.

The green test skein fastened to the inside of the box cover is placed at a distance of 2 feet and the candidate is given the pointed pencil and requested to look along each row of colored patches and when he sees the test color or one of its lighter or darker shades, he is to place the point of the pencil in the opening and punch a hole in the paper beneath. Having completed Test 1, the cover is replaced and the box turned over, exposing Test 2, the rose. The record blank having been inserted and the rose skein displayed, the test proceeds as before.

ADVANTAGES

1. The candidate makes a permanent record of his own color sense.
2. The soiling of the worsteds by constant handling is avoided.

3. The worsteds are divided into two groups: in the first group are placed all the colors mistaken for green by the color-blind; in the second group are placed all the colors mistaken for rose by the color-blind.

4. The comparison of colors by placing two or more together is avoided.

5. The large number of colors used, 128, gives free scope in the detection of all cases of color-blindness.

6. The small size of the color patches, while ample to show the color to the normal eyed, may lead to the detection of a central color scotoma.

7. The tedious method of recording the color sense by pulling out a concealed bangle and writing its number on a blank is avoided.

8. An important color cannot be lost.

9. On account of its symmetry it is absolutely impossible for any but those with a perfect color sense to pass the test.

10. It is the only method by which uniform results can be obtained whether the examination is made by the physician or by the layman.

11. Two or more records of the examination can be made at the same time and the official at headquarters is able to see exactly what colors have been selected to match the test skeins.

I am indebted to Dr. Charles H. Williams of Boston for suggesting the method of threading the worsted.

508 Carleton Building.

A NEW PETRI DISH COVER

C. C. YOUNG, M.S., Lawrence, Kan.

Director, Kansas State Water Survey

The ordinary porous Petri dish top has not given satisfaction in our water laboratory. In an attempt to eliminate the troubles a glaze was put on the outside of a few covers for experimental purposes. We were so pleased with the improved results obtained that hereafter porous tops with glazed outer surface will be used entirely in this laboratory.

These glazed covers combine the good features of both the glass and the ordinary porous tops. They are superior to the unglazed tops in many ways and the cost is no greater.

1. Evaporation of the water from the medium is reduced about 60 per cent., but they are still porous enough to absorb all water of condensation.

2. The glass bottoms are not scratched and ground when the plates are stacked in the incubator.

3. The glazed surface affords a convenient place for marking with a wax pencil. The marks can be rubbed off as easily as they can from glass.

4. The glaze adds much strength to the cover; consequently the breakage is reduced to a minimum.

5. They slip one over the other as easily as glass.

6. There is less danger of contamination, as the glaze protects the porous part of the cover so that material spilled on a plate is not absorbed.

The advantages of this new cover over the old appear to be sufficient to warrant all laboratories filling in their stock with this type.

UMBILICAL CORD OR FUNIS RETRACTOR

W. P. MEGRAIL, M.D., WHEELING, W. VA.

There is probably no more serious or fatal complication to the child during its birth than prolapse of the umbilical cord, which renders an otherwise easy and safe birth one of greatest danger to the life of the babe.

Also there is no other place in which the obstetrician finds himself so helpless to save the life of the child if unprepared for this complication when finding on examination a presenting, pulsating umbilical cord, and a half dilated rigid cervix.

There is usually no sterile catheter at hand, or if there is, it is difficult to thread it with a tape quickly and the babe is going to die in a few minutes unless the umbilical cord is promptly placed where it will be out of the way of the oncoming head.

This simple instrument is constructed of spring steel; 12 inches in length, 5/16 inch in width at the narrowest part, and about 1/60 inch thick except at both ends, where it is 1/8 inch thick, and rounded to prevent the danger of producing a puncture or laceration.

At one end there is a half circle crotch, 3/4 inch in diameter, containing a number of serrations on the inner circle so that it will hold the cord and carry it up into the uterus beyond danger of compression, or if the operator prefers he can use the other end of the instrument and thread it through one or both holes with a tape or strip of narrow bandage and pass it around the cord in the same manner as with the whalebone fillet or the modern catheter or bougie.

The advantages of this instrument are:

1. It can be perfectly and rapidly sterilized.

2. It is quick and easy of application.

3. It combines two instruments in one.

4. It is flexible and will adapt itself to any curve, and yet it occupies less space in the pelvis than a catheter.

Umbilical cord retractor

5. It is inexpensive, light in weight and occupies no space in the obstetric bag, where some appliance should always be found ready for this emergency.

6. It may also be used with advantage in passing a tape around a foot or leg in doing an internal version.

SELF-RETAINING COLLAPSIBLE T-SHAPED CATHETER FOR SUPRAPUBIC DRAINAGE OF THE URINARY BLADDER

W. L. CHAPMAN, M.D., PROVIDENCE, R.I.

Surgeon and Pathologist to St. Joseph's Hospital

At the left of the illustration the catheter is shown folded pencilwise in the grasp of an ordinary dressing or dissecting forceps ready to be introduced into the suprapubic incision.

When the forceps is withdrawn the catheter immediately springs into position with but slight adjustment. Withdrawal is easy on account of the soft material of the catheter. At A and B are shown the oval apertures for drainage which may be readily enlarged with the scissors if desired. In case larger drainage openings are needed the ends of the T arm may be snipped off. The catheter is practical, does not readily become clogged, allows but little leakage around it, may be removed or reinserted with but little pain to the patient, and may be used for prostatic as well as suprapubic drainage. It is made for me by the Davol Rubber Company of this city and may in a short time be obtained from dealers.

Self-retaining catheter for suprapubic drainage of the bladder.

254 Benefit Street.

Hydrobromid of Quinin in Whooping Cough.—I have had a pleasing experience in the use of neutral hydrobromid of quinin (gr. v four times a day in adults). It allays the spasmodic cough, relieves the sense of depression and conduces to rest. It seemed rational, that if it produces so happy an effect, as it often does in Grave's disease, it would be of service in whooping cough and it has proven so with me.—E. A. SATURDAY, SEPTEMBER 19, 1914

RELATION OF VACCINE VIRUS TO POST-VACCINATION TETANUS

From time to time cases of tetanus following vaccination are being reported. These infections have been attributed to various causes; carelessness on the part of the operator, infection of the vaccination wound by uncleanly habits of the patient, a vaccine virus contaminated with tetanus, and, at times, a tetanus-infected wound of another part of the body received about the time of vaccination.

The Pennsylvania State Vaccination Commission¹ have reported on the relation of vaccine virus to tetanus following vaccination. They have given the subject much attention and some important facts have been determined. Of especial interest were the data with regard to the period of incubation and the case mortality of tetanus following vaccination, as compared with tetanus in general. It was shown before the commission that of 870 cases of tetanus studied by Anders and Morgan, the disease developed in 568 between the first and tenth days after infection. In 302 cases the incubation period was from ten to twenty days or more. Of the 568 cases with an incubation of ten days or less, 419 were fatal, giving a mortality of 73.8 per cent. Of the 302 cases with an incubation period of more than ten days, 45 patients died, a mortality rate of only 11.5 per cent.

The significance of these figures, in their bearing on vaccinal tetanus, is at once obvious. The great majority of cases of vaccinal tetanus have an incubation period of over two weeks, counted from the date of vaccination, while the fatality of vaccinal tetanus is 78 per cent., as shown by Wilson's² 52 cases. This closely corresponds with the mortality of 73.8 per cent. found by Anders and Morgan for tetanus with an incubation period of less than ten days, and hence lends much weight to the assumption that cases of vaccinal tetanus contract their infection subsequent to vaccination and not from the vaccine virus.

These data and the inferences drawn therefrom, however, while extremely suggestive, are not convinc-

ing unless supported by other data, such as laboratory experiments. These latter, up to the present, have been lacking in a measure. In a recent bulletin of the Hygienic Laboratory, however, Francis² reports the results of extensive laboratory studies on tetanus, especial attention being given to the relation of vaccine virus to tetanus.

Under the Federal law regulating the manufacture and interstate sale of viruses, serums, etc., it has become necessary to examine a large number of samples of vaccine virus. Since the law went into effect, in 1902, there have been examined in the Hygienic Laboratory over 1,500,000 doses of vaccine virus with especial reference to the presence of tetanus spores. In not a single instance has the tetanus bacillus or its spore been found in vaccine virus.

In many instances, samples of vaccine virus of the same lot as that used in cases of vaccinal tetanus have been examined, but the result was negative for the presence of the tetanus organism. For this reason, and to be sure of his materials, Francis resorted to artificial contamination of vaccine, in order to carry out his experiments. He discusses well-known difficulties encountered in growing tetanus bacilli from vaccine virus, and shows that no single cultural method or animal test will invariably detect the presence of tetanus, but that a combination of different methods is effective.

A number of attempts were made to infect monkeys with tetanus by vaccinating them with a virus which had been heavily contaminated artificially with tetanus spores, but in no instance did the animal develop tetanus, although typical takes were produced. From these experiments it would appear that even if virus contains tetanus organisms, it is improbable that infection with tetanus will follow. The great importance of guarding the vaccination site from contamination cannot, therefore, be too greatly emphasized. Interesting information is given with regard to the results of cleanliness in collecting vaccine virus from a calf that had been vaccinated with virus artificially contaminated with tetanus spores. After carefully washing one portion of the vaccinated area with sterile water and brush, the virus was collected under aseptic conditions from the washed area and also from the unwashed part. The virus from the unwashed area showed, when examined culturally, tetanus in 100 per cent. of the cultures, while cultures from the washed area gave only 22 per cent.

If washing the vesiculated skin of the calf's abdomen with sterile water is sufficient to remove 75 per cent. of the tetanus spores artificially implanted thereon, it would certainly seem that before vaccinating, we should be able to remove 100 per cent. of tetanus spores from the smooth skin of the arm, should

1. Report of the Pennsylvania State Vaccination Commission, March, 1913.

2. Francis, Edward: Laboratory Studies on Tetanus, Bull. Hyg. Lab., 95, August, 1914.

they chance to be present. With a tetanus-free virus and a tetanus-free site for vaccination, and with reasonable after-care, there should be no vaccinal tetanus.

In spite of the evidence submitted by Francis, we should not neglect rigid asepsis in performing vaccinations in the belief that the vaccination sore will not absorb tetanus infection. His work should serve as a warning to us not to be too ready to put blame on the virus, the operator or the patient if we should be so unfortunate as to have a case of tetanus following vaccination. To put the blame in the wrong place does not alleviate the suffering of the patient or relatives in the least. It does allow a case to go into medical history which leaves the true avenue of tetanus infection unsuspected, to cause perhaps a repetition in another case at some future time.

Most of the accidents associated with vaccination can be attributed to the failure on the part of the physician or patient to realize that vaccination is a surgical operation and that the vaccine wound is a wound that must receive the same care and asepsis that any other operation wound should receive.

THE ADJUSTMENT OF THE DIETARY TO ECONOMIC CONDITIONS

The migration of a large fraction of the population of the civilized parts of the world from the country to the cities is one of the phenomena attending the "industrialization" of modern nations. Whereas formerly the city was essentially a center for trade and office life, of late the factory with its large working population has become an adjunct of city life. From the point of view of nutrition, which plays a dominant part in determining the fitness of the individual for work, it is unfortunate that the less opulent laboring classes should be drawn away from the region of cheap food in the country to homes where new standards of living are imposed on them. The altered distribution of the population has brought with it certain problems of nutrition that cannot be dismissed as inconsequential or solved by restrictive legislation. Economic laws sometimes are far more effective than educational propagandas or governmental interference.

The industrial worker who migrates from the country to the city, like the immigrant, soon finds that he must alter his accustomed diet. The simplicity of an adequate diet obtainable in the country regions cannot readily be continued in the city. The cheapest articles of food, such as bread and potatoes, available in the larger centers, do not satisfy the protein requirements sufficiently as a rule. But even if cheap forms of protein were procurable, the demand for a special source, namely, meat, soon becomes a dominating factor in the selection of the ration. Meats, whether of mammals, birds or fishes, have always

entered prominently into the dietary of the well-to-do; and in this country, where the tendency to wipe out the distinctions between social classes is always in operation, the poor and the less favored groups are continually striving to imitate the ways of their more fortunate neighbors. A national sentiment fosters this ambition in a country where "every man is a king." The urban workman wants good cuts of meat not because they are absolutely indispensable to health, but because the example of his neighbor has encouraged the habit. It is quite different on our farms and in rural communities, where local produce enters more largely into the home.

With an impending rise in price and increasing scarcity of meat making itself felt throughout the country, and with the growing tendency of the industrial workers coming from the country to the cities to try to provide the table which is demanded by their well-to-do neighbors, a household problem inevitably arises. Either the dietary habit must be materially changed to include a different type of ration—a scheme almost impossible of accomplishment where food customs are in part dictated by usage—or retrenchment in expenditures must be sought in some other way.

At present the cheapest articles of food include potatoes, peas and beans, and certain cereals in the form of coarse bread; cabbage forms a cheap green vegetable; among animal products, milk and cheese are comparatively inexpensive; fish furnish the cheapest forms of flesh foods; and dried apples are among the cheapest fruits. Expensive butter can be in part replaced advantageously by less expensive, yet thoroughly wholesome animal and vegetable fats. Beef, which is always expensive, might well be replaced more liberally by fish than it has been in the past. Without having statistics at hand to support the statement we nevertheless venture the opinion that the popularity of fish is growing rapidly in America. Potatoes are not yet competing with the cereals as extensively as they might well do; but cheese is likely, as we have intimated before,¹ to find increasing favor.

The adequate dietary is a decidedly flexible affair, and it is well that this fact should become widely inculcated. The idea that even radical departures from acquired food habits are likely to lead to nutritive disorder and decreased efficiency needs to be eradicated. The foods of nations vary widely and yet support creditable human specimens. When once this fact is thoroughly appreciated there will be less dismay when a rise in the price of some supposedly indispensable product is announced. The adjustment of the dietary to the pocketbook will be further facilitated when intelligent marketing becomes recognized as a household art that deserves cultivation.

SODIUM VERSUS POTASSIUM COMPOUNDS

The beds of potassium salts in Stassfurt and other localities in Germany have been shut off from commerce by the war, and we are threatened with a shortage of potassium salts. As the supply of sodium salts is practically inexhaustible in this country, why should we not prescribe them? While many of us in prescribing the bromid have fallen into the habit of prescribing potassium bromid, we know of no reason why sodium bromid would not be just as good, at least in practically all cases.

Though it may be difficult to get out of the habit of prescribing potassium iodid, it is doubtful whether it is any more effective than sodium iodid. Sodium acetate could easily be substituted for the potassium acetate. The potassium salts are slightly more stable than the sodium salts, but in general the salts of the one base have no marked therapeutic advantage over the corresponding salts of the other. The potassium compounds are more active and are said to possess a more marked diuretic effect; but the sodium salts are less depressing to the heart and in some instances less disagreeable to the taste.

In this matter we have to consider the therapeutic effect, the side effects and the pharmaceutical reasons for preference of one salt over the other. In the case of the bromids and the iodids the therapeutic effect is derived from the negative element; that is, iodine or bromine. This being the case, it is a matter of indifference whether we use potassium bromid or sodium bromid, or whether we substitute sodium iodid for potassium iodid, except that the relative amount of iodine and bromine is a little greater in the sodium compounds than in the potassium. With regard to side effects, sodium compounds are thought to be less irritating to the stomach, and in large doses potassium bromid or iodid might be somewhat more depressing to the heart. With regard to physical properties, sodium iodid and bromid are less permanent in the air, but this concerns the pharmacist more than the physician, as these salts should be prescribed in solution.

Potassium acetate and citrate are used as diuretics, but can be conveniently replaced by sodium salts, as the therapeutic aim is reached just as well by prescribing sodium citrate or acetate as by the use of the corresponding potassium salts. Here there appears to be no difference on account of side actions or of physical properties.

It seems possible that the vogue of the potassium compounds has a historical cause, and is at present due largely to habit. The earliest source of sodium carbonate, from which most of the other sodium salts are derived, was the ashes of seaweeds; the earliest source of potassium carbonate was wood ashes. Wood ashes were plentiful and cheap, inland as well as on the seacoast; hence the natural preference for potas-

sium compounds. It is of interest now to recall that the first impetus to the general employment of sodium salts was given by another devastating war. During the French revolution the important soap industry in France was seriously crippled because all the available potash in France was required for gunpowder, and the importation of soda-ash made from kelp and wrack was suspended. A prize offered by the Directory for the best method of producing sodium carbonate from sodium chlorid was won in 1794 by Le Blanc. The sodium carbonate produced by his process, however, was not cheap enough to withstand the competition of the Spanish kelp-ash, which was imported into France as soon as commercial relations with other countries were reestablished, and the unfortunate Le Blanc died by his own hand in a poorhouse. The value of one of its by-products, hydrochloric acid, saved the Le Blanc process from extinction, and it is still extensively used in Great Britain; but the price of sodium carbonate did not become reduced to anything like its present level until the Solvay process came into general use in the latter part of the nineteenth century.

How much effect, if any, these commercial factors have had on the therapeutic use of potassium compounds is not easy to prove. It seems probable, however, that the original high cost of sodium carbonate, the source of most other sodium compounds, has not been without influence on pharmacy. The pressure of necessity caused by the present war probably will have the effect of rationalizing this branch of our therapeutics. The sodium salts, being less irritating than those of potassium, will be given the preference except in cases in which the latter are specifically indicated.

INDUSTRIAL HEALTH

The importance of the problem of industrial sanitation is gradually becoming more fully realized. Some employers, indeed, even yet apparently take the ground that, if workmen are willing to labor under insanitary conditions, it is no concern of their employers. The New York State Factory Investigating Commission, which has carefully studied the conditions under which about two hundred thousand wage-earners work, reports that "there is a tendency on the part of many employers to economize not only in matters of legitimate expense but also in space, light, air, and certain other safeguards to the health and lives of the workers." The report of the State Board of Health of Louisiana indicates that over 50 per cent. of all the manufacturing establishments in the state are in "poor" or "bad" sanitary conditions. Most states have no available figures, but New York and Louisiana are so far from each other geographically, economically and socially, that, for lack of better, we may take these two reports as an index of industrial health conditions generally throughout the United States. On the whole,

however, we believe that with each year employers tend to appreciate more and more the commercial value to them of sanitary working conditions for their employees.

B. S. Warren of the United States Public Health Service, who has been deputed as sanitary adviser to the United States Commission on Industrial Relations, points out¹ that the false economy involved in neglect of sanitation inevitably leads to greatly lessened efficiency and is thus really expensive for the employer in the end. The highest efficiency is possible only when the health of workers is favored by good air and light, proper arrangement of hours of labor and the maintenance of the safeguards of health.

With regard to hours of labor particularly, some recent experience is valuable as indicating that shortened hours of labor may actually conduce not only to the health of employees but also to greater production. In the Engis Zinc Works the hours of labor were cut down from twelve to eight per day, yet the men earned as much and did as much work in eight hours as they did formerly in twelve. Besides there was a marked decrease in the calls on the sick fund, the men no longer felt the need of stimulation, and sobriety was markedly increased. Almost the same thing happened at the Zeiss Optical Works in Germany. Abbe kept a careful record for the years when the plant was operating on a nine-hour day. When the working day was reduced to eight hours, the record showed the men earned over 3 per cent. more than during the previous year, the output of the work was increased 3 per cent. and the power-plant was able to shut down an hour earlier, thus effecting a very material saving in fundamental expense. The record was for 233 men at an average age of 31 years, and many different occupations on a piece-work basis were represented in the shop.

Both employers and employees need to be convinced of the evident fact that the healthy man is the most efficient and the cheapest employee and that any reasonable expense to maintain him in health is a profitable investment. The public health worker can act as a mediator between capital and labor and aid greatly in the amicable adjustment of the prevalent industrial strife. Warren suggests that it is regrettable that medical men have neglected so long to teach methods of disease prevention. "Their study must include the total environment and, if possible, untangle the bundle of influences that in effect are producing disease more surely than the germs which are the direct agents." Physicians as impartial investigators can present the facts and suggest the remedies to both sides and thereby accomplish great good for social improvement and public health.

METABOLISM IN FEVER

The construction of the ideal dietary schedule for fever patients will not be accomplished until the nature of the disturbance of metabolism in diseases attended with rise of body temperature is clearly ascertained. It is agreed that the increase in total metabolism in fever is ordinarily associated with increases in protein metabolism. The cause of the latter, however, has given rise to much speculation and contradictory views. At least three explanations of the higher catabolism of protein have been ventured. First, it has been ascribed to the high temperature. We have previously referred to the investigations of Graham and Poulton¹ on this point. Living on a ration abundant in carbohydrates whereby they easily reached a low plane of nitrogenous equilibrium, these investigators subjected themselves to heated steam sufficient to raise their body temperature to as high as 40 C. (104 F.). During this artificial state of high temperature no alteration whatever in protein metabolism was noted; therefore the physical factor of rise in body temperature cannot be postulated as the primary cause of the considerable and constant augmented destruction of protein noted in true clinical fevers.

As a second cause of the increased protein metabolism noted in fevers an alleged condition of undernourishment of the body cells has been postulated, an impoverishment of the store of glycogen in particular being held responsible. It is, of course, a well-known fact that lack of carbohydrate occasions increased destruction of protein in the organism under any condition. It was the distinct merit of Shaffer and Coleman in this country to have attempted to forestall the depletion of the non-protein energy reserve of the body in typhoid fever by instituting their now widely known high-calorie feeding in this disease.² With a diet abundant in carbohydrate and fat it was shown that, even with a low protein intake, patients may be maintained in almost complete nitrogenous equilibrium throughout the duration of the typhoid infection. The brilliant results achieved raise the question whether the success is due to the provision for a compensatory regeneration in the organism or to a prevention of what may here be referred to as the third possible cause of protein catabolism in fever, namely, destruction of protein by the action of the special toxins produced.

Dr. Rudolph A. Kocher³ of Baltimore, working in Friedrich Müller's clinic at the University of Munich, has questioned the interpretation of the results of Shaffer and Coleman. He notes that the excellent

protein-sparing results achieved by their high carbohydrate diets were as a rule not attained until the fever had progressed into the second or third week of the disease. It is quite conceivable, as Kocher maintains, that the favorable effect does not manifest itself until after the first or severe stage of the infection; that is, until a period when the organism has acquired ability to resist the deleterious consequences of the noxious agencies. Accordingly Kocher has reinvestigated the protein metabolism in the earlier stages of febrile disease. He reports that even very liberal diets yielding as much as 80 calories per kilogram cannot retard the protein catabolism in the early period of the fevers as they do later. The conclusion is therefore forced on Kocher that, contrary to some of the more recent contentions of other clinical students of metabolism in fever, a considerable destruction of protein not chargeable to the high temperature *per se* or to insufficient energy intake, actually takes place. In the words of Kocher, infectious fever must be pictured as a clinical syndrome of rise in temperature and protein destruction, the latter perhaps due to special (toxic) effects on the protoplasm. It should be clearly noted that this conclusion in no way contra-indicates the essential changes in the dietary that have found their way into practice in this country, especially in the management of typhoid fever. More liberal feeding in suitable cases has come to stay. It merely brings the question of the quota of protein desired into the foreground once more.

THE ABSOLUTE AND PERCENTILE AMOUNTS OF SUGAR IN THE BLOOD

In the chemical pathology of sugar metabolism, there are numerous anomalies which have long been confusing because of their apparently conflicting character. The hyperglycemia of the typical diabetic individual may be regarded as an undisputed fact. There are, however, cases of glycosuria in which the percentage of sugar in the blood is certainly not increased above the normal. It is these which have furnished the basis for the claims of a form of renal diabetes in which the chief distinguishing characteristic appears to be an increased permeability of the kidney for blood-sugar.¹

To help explain the presence in certain individuals of glycosuria without hyperglycemia, and, conversely, the absence of glycosuria when hyperglycemia is present, Epstein and Baehr² have offered a new hypothesis, based on a series of experiments in the Pathological Laboratory of the Mount Sinai Hospital in New York City. Their observations on the hyperglycemia following hemorrhage lend themselves to a new interpretation. It has long been known that after removal

of blood the concentration of sugar in the circulating fluid subsequently increases. Some investigators incline to attribute the resulting hyperglycemia to psychic causes. It is doubtless true that an increased percentage of sugar results from the manipulation and operative interference—an increase probably associated with the adrenal disturbances to which we have referred editorially in the past.³ Very marked hyperglycemias following blood-letting doubtless involve such factors. But it is quite possible to obtain smaller increases in the percentage of sugar even when the psychic disturbances are avoided. Epstein and Baehr have now pointed out that the increase in the percentage of sugar in the blood is indicative only of a relative, that is to say, percentile, but not an absolute, hyperglycemia. Although the percentage concentration rises after bleeding, the total amount of sugar present in the circulation, calculated on the assumed blood-volume, remains surprisingly constant. For example, in one animal, the total blood-volume before the bleeding was computed at 105 c.c. (5 per cent. of the body-weight). The amount of blood drawn was 30 c.c.; in other words, 75 c.c. of blood was left in circulation. The percentage of sugar in the blood as drawn was 0.105 per cent.; two hours after the bleeding the sugar-content rose to 0.154 per cent. By comparing the total volumes of blood in the animal before and after the bleeding, they are seen to bear the ratio to one another approximately as 3:2. On the other hand, the percentages of sugar in the blood before and after the bleeding are to one another as 2:3. In other words, the percentage of sugar in the blood is inversely proportional to the blood volume.

The increase in the percentage of sugar in such experiments with hemorrhage is usually seen to bear a striking relationship to the proportion of blood left in circulation after the bleeding. To test the hypothesis regarding the constancy of the absolute amount of blood-sugar, Epstein and Baehr also replaced the blood withdrawn by an equal quantity of physiologic saline solution. Under these conditions no change in the percentage concentration of the sugar occurs; for in most cases the sugar concentration of the diluted blood rapidly rises to what it was before the hemorrhage. In other words, the total sugar in the circulation remains unchanged.

Commenting on the cases of so-called renal glycosuria, the New York investigators remark that these may be dependent on an increase in the total blood-sugar and that the absence of any hyperglycemia could be accounted for by the existence in these individuals of an abnormally large blood-volume. They suggest the advisability of studying blood-volumes and computing therefrom the total blood-sugar in cases of diabetes mellitus. It seems somewhat far-fetched to

1. Renal Diabetes, editorial, THE JOURNAL A. M. A., Nov. 1, 1913, p. 1632.

3. Newer Views of the Functions of the Adrenals, editorial, THE JOURNAL A. M. A., July 25, 1914, p. 322.

conclude, as Epstein and Baehr propose, that in such studies may lie the explanation for the disproportion which occurs so frequently in this condition between the degree of hyperglycemia and the intensity of the glycosuria. It is not easy to understand how any tissue-cells can distinguish or appreciate the total amount of circulating sugar, whereas it is quite in line with other chemical experience to find modifications in physiologic reaction induced by altered concentration of components of the blood. The fact of the apparent normal constancy of the absolute quantity of circulating sugar in individuals is of interest, whatever the validity of the appended theory may be.

Current Comment

SCIENTIFIC MEDICINE IS "PRACTICAL" MEDICINE

A letter received by THE JOURNAL reads: "What is the best treatment for diabetes mellitus?" That is all. There is nothing unique about the letter or the question; it is a sample of queries that come every few days, and illustrates the fact that some men are still treating names. There is a popular notion that a definite treatment has been laid down to correspond to every disease name and that having learned the name of the disease, one has but to apply the treatment prescribed in the text-book. The idea is crude and fallacious that when the diagnosis is made, the treatment is easy, the fallacy arising from the fact that diagnostic analysis is not carried far enough and names alone suffice without a determination of the pathologic condition in all its details. Our present querist appears satisfied with the name "diabetes," qualified, to be sure, by the adjective "mellitus." A little reflection should indicate that this name includes a number of different conditions, the presence or absence of which must decide the plan of treatment to be adopted. Thus diabetic patients differ much in their tolerance of carbohydrates. Some have acidosis and are threatened with coma, others are in no immediate danger. Before deciding on the treatment for any disease the actual conditions requiring relief must be determined, and then the appropriate remedy prescribed. In the case of diabetes it must be determined to what extent carbohydrates can be tolerated by the individual patient, as there may be present so great a degree of acidosis that to exclude carbohydrates would be dangerous. If the danger is from intoxication by sugar in the blood, the diet must be regulated to reduce the sugar to a minimum. If acidosis threatens, the proper remedies must be chosen to avert the danger. We are taking this particular letter and the disease it specifies to emphasize a principle; for the principle applies to other diseases—to all diseases, in fact. There is no specific treatment for typhoid fever; even the diet of a typhoid patient must vary according to conditions. The same is true of pneumonia: what will benefit one pneumonia patient may injure another. Those who conduct the so-called "practical journals," and more particularly the readers

of these journals who love so-called "practical matter," should note that more is required of the physician than a diagnosis of the disease by name only. If it were otherwise doctors would not be necessary, for the majority of people can tell a case of whooping-cough, of measles, of typhoid fever, and of other common diseases. The people would need merely to look in a book and see the treatment. The doctor is supposed to treat, not a name, but the individual patient and the particular conditions in that patient. There is no "best treatment for diabetes," but what is best for each patient must be settled first by determining the actual pathologic conditions in the individual affected.

NEW FACTS ABOUT THE CEREBROSPINAL FLUID

There has taken place of late a commendable revival of interest in the normal and morbid physiology of the cerebrospinal fluid. A superabundance, rather than a diminution, of this fluid is the predominant factor in every morbid process of the central nervous system in which it is affected. In hydrocephalus, congenital and acquired, and in the various forms of meningitis, the excessive accumulation of fluid not only plays a part in the clinical expression, but also is often the determining factor in the high mortality-rate of these diseases. That there must be a disturbance of the balance between secretion and absorption to account for the abnormal increase is self-evident, but which of the two factors is the more potential has been a matter of conjecture. As a contribution to this problem, the work of Dandy and Blackfan¹ is significant. They were able to demonstrate by the production of an artificial hydrocephalus, not only that practically all the fluid was generated within the ventricles, but also that there was no absorption within the ventricles. Furthermore, by the injection of phenolsulphonophthalein, these observers were able to establish a normal standard for the excretion of phenolsulphonophthalein after its injection into the ventricles or subarachnoid space, and have further used the phenolsulphonophthalein test to distinguish clinically between two forms of hydrocephalus, one with, and the other without, obstruction to the ventricles. In a similar series of experiments Frazier was able to demonstrate by the phenolsulphonophthalein test that the venous channels play the most important part in absorption, and that the lymphatic absorption is a negligible factor. When the phenolsulphonophthalein was injected into the ventricle, the dye-impregnated cerebrospinal fluid appeared in the torcular herophili in two minutes, whereas it took almost twelve hours for it to reach the lymph-nodes of the parotid group when injected into the subarachnoid space. Of the earlier contributions, the most important by far were those of Faivre, Luschka, Francini, Levaditi and Mott, who by histologic evidence have shown that the cerebrospinal fluid is a secretory product of the choroid plexus, or as Mott describes it, the "chorioid gland"

1. Dandy, W. E., and Blackfan, K. D.: An Experimental and Clinical Study of Internal Hydrocephalus, THE JOURNAL A. M. A., Dec. 21, 1913, p. 2216.

with an external secretion and an internal destination. Dixon and Halliburton² and Frazier³ have been conducting independently a series of experiments in their laboratories on the hypothesis that inasmuch as the choroid plexus is a gland with a secretion, its function might be increased or decreased by certain influences. Dixon and Halliburton found that the injection of brain extract and more particularly the extract of choroid gland caused a hypersecretion, attributed to the specific action of some substance—possibly a hormone product of brain metabolism—on the secretory cells of the choroid gland. Of greater significance is the finding by Frazier of a substance which has a distinctly inhibitory effect. In marked contradistinction to all other glandular extracts, the extract of the thyroid gland was unique in that it caused a continued and prolonged decrease in the flow of cerebrospinal fluid, wholly irrespective of the effect on blood-pressure. It is often a far cry between laboratory demonstration and clinical application, but these experiments offer a hope of dealing with the problem of perverted secretion at its source. This, it seems, is the significant feature of these researches.

ONCE MORE THE LEAGUE FOR MEDICAL FREEDOM

The National League for Medical Freedom has again exercised its divine right of protesting against anything and everything beneficial to the public health. As those familiar with the history of the League know, protesting is one of the best things it does. Readers of *THE JOURNAL* may recall the first appearance in the public eye of this organization which suddenly burst, meteor-like, on the public, through the medium of half and full page display advertisements in the leading newspapers of the country, setting forth the awful dangers and deep laid plots of "The Medical Trust." Incidentally, as nearly as can be estimated, this campaign, costing about \$50,000, was inaugurated before the newly organized "League" had any membership that any one had ever heard of. Just where the money came from to finance such an extensive campaign has never been explained. For several months during the summer and fall of 1910, the "League" protested to its heart's content, after which (whether due to exhaustion of its funds or of its lungs, it is impossible to say) it lapsed into the condition immortalized by Grover Cleveland as "innocuous desuetude." It has not been heard of since except that in a few localities where particularly ardent disciples dwelt and kept the fire burning on the altar, it has intermittently lifted up its voice in protest against everything in the way of sanitary progress and disease prevention, claiming in all cases that the efforts of physicians to diminish disease are a diabolical and deep laid scheme on the part of the "medical trust" to secure complete control of the nation. Just why the "medical trust" should want control or what it would do after it got it, the League has never divulged

any more than it has its proof of the existence of such a "medical trust." These things are locked deep in the bosoms of the devoted partisans who make up this organization. The latest protest on the part of the League is directed against the United States Bureau of Education. In the report of the Commissioner of Education for 1913, in a series of twenty-five or thirty papers by experts on the progress of education in different fields, appears an able summary of the progress in medical education, by the secretary of the Council on Medical Education of the American Medical Association. This Council, it is hardly necessary to state, has for eight years past carried on an extensive study of medical education in this country. It appears that about the time this report was being prepared, an Iowa member of the National League for Medical Freedom wrote a paper objecting to the medical inspection of schoolchildren, which was sent to the Commissioners of Education with the demand that it be printed as a part of the Bureau of Education publications. The United States Commissioner of Education, it seems, declined to publish the article, wherein the National League for Medical Freedom sees evidence of a dark and awful conspiracy between the American Medical Association and the United States Government, and proceeds to protest. Of course, there may be such a plot, although the evidence on this point seems to be conspicuously lacking; but one explanation for the action of the Bureau of Education has apparently not occurred to the National League for Medical Freedom. It is barely possible that the reason why the report on medical education was gladly accepted and the tirade on medical inspection of schools was declined was that the report was the result of eight years of careful study, while the "protest" was the usual jumble of vague charges, exaggerated statements and unsupported assertions. In a word, it is barely possible that the Bureau of Education acted as it did because one paper was worth publishing and the other was not. This explanation has evidently not occurred to the National League for Medical Freedom, and simple as is this explanation, it is hardly to be expected that it would.

THE WINE OF CARDUI LIBEL SUIT

In last week's issue, attention was called to the fact that the manufacturers of "Wine of Cardui" have filed suit against the American Medical Association and the editor of *THE JOURNAL*. The Chattanooga newspapers, in noting the fact, state that the Chattanooga Medicine Company has engaged a firm of attorneys in Chattanooga, another attorney in Knoxville, still another in St. Louis and a fourth in Chicago, giving the names in each case. Such wholesale retaining of lawyers as that described probably comes high, but doubtless the Chattanooga Medicine Company can afford it. Defrauding the sick has in the past been an easy road to wealth, although we venture to prophesy that it is likely to be less easy in the future. The Wine of Cardui concern hires the lawyers, but the ailing women of the country pay the bill.

Medical News

ILLINOIS

Teachers Must Be Examined.—The Board of Education of Springfield stated that all teachers in public schools must undergo physical examination and obtain certificates of health before being allowed to take positions.

Chicago

Faculty Changes.—Dr. Daniel A. K. Steele has been appointed senior dean and head of the department of surgery in the College of Medicine of the University of Illinois; Dr. Charles Spencer Williamson, professor of medicine and head of the department; Dr. Charles Sumner Bacon, professor of obstetrics and head of the department of obstetrics and gynecology; Dr. Julius Hays Hess, associate professor of pediatrics and head of the division of pediatrics; Dr. Norval Pierce, professor of otology; Dr. Joseph C. Beck, associate professor of laryngology and rhinology and head of the division; Dr. Oscar Eugene Nadeau, instructor in surgical pathology; Dr. A. O. Shoklee, associate professor of pharmacology; Dr. Roy L. Moodie, instructor in anatomy and Dr. C. S. Smith, instructor in physiological chemistry.

INDIANA

State Society Meeting.—The annual meeting of the Indiana State Medical Association will be held in Lafayette, September 23 to 25.

Suit to Get Physician's Estate.—The suit for \$80,000 against the estate of the late Dr. Michael A. Jordan, Logansport, brought by John Jordan, Nolen, claiming to be the natural son of Dr. Jordan, is said to have been compromised for \$8,000.

Personal.—Dr. Brown S. McClintic, Peru, has received an appointment as surgeon under the American National Red Cross and will sail for Europe this week.—Dr. Andrew W. Smith, Hammond, has been appointed director of athletics in Throop College, Pasadena, Cal.—Dr. Charles Melvin Mix, Muncie, has returned from abroad.—Dr. James H. Walker, Henryville, has been appointed social superintendent of the Indiana State Reformatory, Jeffersonville, vice Prof. Rufus B. von Klein Smid, elected president of the University of Arizona.—Dr. W. N. Williamson, Indianapolis, has been appointed supreme medical examiner of the Order of Larks.

IOWA

Society Offers Service.—The Fort Madison Medical Society, at its meeting August 31, offered the services of its members free to the school board for the examination of school-children.

Demand for Small-Pox Pamphlet.—The State Board of Health of Iowa recently issued an edition of 42,000 copies of a bulletin regarding small-pox, and during the first week after the issue 37,000 copies were asked for.

Tuition Fees Not Raised.—An official statement from the State University of Iowa says that the tuition fees to both the College of Medicine and the Homeopathic College of Medicine for the four years, respectively, are \$60, \$50, \$50 and \$60. Reports previously sent in erroneously gave the figures as nearly twice those amounts which were published in the Educational Number of THE JOURNAL.

Personal.—Dr. Charles E. Glynn has been appointed president of the Davenport Hospital.—Dr. Vernon L. Treynor has been elected medical inspector of the Council Bluffs schools.—Dr. Percival B. Glew, Des Moines, has been appointed instructor in physical hygiene in the public schools of that city.—Drs. Mary K. Heard, Iowa City, and Louis G. Patty, Carroll, have returned from abroad.

KENTUCKY

Antityphoid Inoculation.—At the request of Senator James, Surgeon-General Rupert Blue, U. S. P. H. S., is forwarding a sufficient supply of antityphoid serum to Pineville for the inoculation of 400 persons. Typhoid fever is prevalent in camps around Pineville.

Personal.—Dr. Joseph N. McCormack, Bowling Green, who has been ill for several months, recently underwent an operation at Rochester. His many friends will be glad to know that he is doing well, and that the outlook is promising that he will soon be restored to health.

Campaign against Trachoma.—The recent government survey showed about 250 cases of trachoma in Jefferson County outside of Louisville, 75 per cent. being curable. Wide-spread infection is present also in Breathitt, Clay, Jackson, Lee, Leslie, Onsley, Perry and Clark counties, almost every county in Kentucky being more or less affected. The State Board of Health has accordingly prepared a proclamation excluding from the schools all children with trachoma until they have been treated and pronounced cured. In Louisville free treatment is to be given at the Emergency Hospital and free transportation will be afforded the patients to the hospital. Dr. Mullins of the U. S. Public Health Service will come to Louisville to take personal charge of the work. Each patient will be expected to remain in the hospital for a week or ten days, and the course of the case will be supervised by the physicians or a nurse for several weeks after the patient returns home. Teachers are to be instructed in the symptoms of trachoma and given authority to send home any child with suspicious sore eyes. The children will not be allowed to return until pronounced free from infection after medical examination.

LOUISIANA

Home from Abroad.—Dr. and Mrs. H. F. Ader and Drs. Robert C. Kemp and John A. Caruthers, Baton Rouge, have returned from Europe.

Dispensary Open.—It has been decided by the board of directors of the Sickles Fund for the Dispensing of Medicine to the Poor to open an additional dispensary at the Touro Infirmary, New Orleans.

Personal.—Dr. Frederick W. Parham has resigned from the Board of Administration of Tulane University of Louisiana, in order to accept the chair of surgery in the New Orleans Polyclinic for the coming session.—Dr. Edmund D. Martin has been appointed to the chair of gynecology in the New Orleans Polyclinic.

Maternity for Touro.—The Touro Infirmary, New Orleans, will build a maternity hospital through the beneficence of Mrs. Henry Newman, who has donated \$25,000 for the purpose. The building is to be known as the Henry Newman Maternity Hospital, as a memorial to the donor's late husband.

Medicine Practice Act.—At the recent assembly of the Louisiana State Legislature a very complete medical practice act was passed. One of the features embodied in the act is a physician for examination in the following branches: "Anatomy, physiology, chemistry, obstetrics, gynecology, physical diagnosis, surgery, pathology, materia medica, theory and practice of medicine and hygiene, providing that any person not using internal medication in his or her practice shall be exempt in examination in materia medica." In a concluding section there is a provision: "That nothing in this act shall be construed as applying to the practice of osteopathy or dentistry, or as effecting or changing existing laws on these subjects."

MARYLAND

Personal.—Drs. Charles W. Hartwig and Ridgely B. Warfield, Baltimore, have returned from abroad.—Dr. Louis A. Sexton, newly appointed admitting physician and third assistant superintendent of the Johns Hopkins Hospital, Baltimore, assumed his new duties September 11.

New Hospital Opened.—The Du Pont Maternity Hospital, erected at Cambridge, through the generosity of Mrs. Alfred I. Du Pont of Wilmington, Del., has been opened to the public, although the formal opening will not occur until later. The building has cost about \$35,000, the gift being made through Dr. Brice W. Goldsborough. It is a three-story brick building with concrete floors. It is erected near the Cambridge-Maryland Hospital, with which it is connected by an inclosed corridor. There are two wards with eight beds in each and nine private rooms.

Banner Centennial.—The following Baltimore physicians composed the Medical Relief Committee during the Star Spangled Banner Centennial, September 6 to 13, and rendered assistance to those who were injured or ill: Dr. George L. Wilkins, chairman, and Drs. John W. Chambers, Thomas R. Chambers, Thomas S. Cullen, Cecil W. Vest, William S. Baer, Alexius McGlannan, John D. Blake, Herbert C. Blake, George A. Hartman, Frank J. Kirby, Robert Parker Bay, Thomas J. O'Donnell, Joseph E. Gichner, John R. Abercrombie, Albert T. Chambers, G. C. Threine, Walter D. Wise, Archibald C. Harrison, D. Webster Cathell, John Staige

Davis, William T. Watson, George Heller, Archibald M. Shipley and Monroe A. Maas.

MASSACHUSETTS

Personal.—Dr. Vincent Y. Bowditch, Boston, is reported to be at Liverpool awaiting passage to the United States.—Dr. Edward P. Worth, Edgartown, has been appointed medical examiner for Dukes County.

Home from Europe.—Drs. Francis D. Donoghue, Boston; Rufus A. Kingman, Brookline; George B. Buehler, Cambridge; Dr. and Mrs. Edward F. Himmins, Boston, and Frank B. Granger, Boston, have returned from Europe.

Hospital Open.—The new St. Elizabeth's Hospital, Brighton, opened September 1. The building is fireproof, three stories in height, has been erected at a cost of a quarter of a million dollars and has accommodations for more than two hundred patients. Dr. John R. Slattery is superintendent of the institution.

MICHIGAN

Personal.—Dr. Emil Amberg, Detroit, and Collins H. Johnston, Grand Rapids, have returned from abroad.—Dr. Fritjof E. Berge, Grand Rapids, announces his intention of remaining in England for considerable time.

Board of Health Train.—The trip of the Michigan health train just finished is said to be the most successful expedition thus far undertaken. During the month, the train was exhibited to more than 40,000 people.

State Medical Society Meeting.—The forty-ninth annual meeting of the Michigan State Medical Society was held in Lansing, September 10 and 11, under the presidency of Dr. Guy L. Kiefer, Detroit. Grand Rapids was selected as the meeting place for 1915 and the following officers were elected: president, Dr. Reuben Peterson, Ann Arbor; vice-presidents, Drs. Louis W. Toles, Lansing; Alfred W. Hornbogen, Marquette; Colin D. Munro, Jackson, and Vernon A. Chapman, Muskegon; counselor for third district, Dr. Starr King Church, Marshall; delegates to the American Medical Association, Dr. Louis J. Hirschman, Detroit; and Herbert E. Randall, Flint; and alternates, Drs. Jacob D. Brook, Grandville, and Alford E. W. Yale, Pigeon.

MINNESOTA

Home from Abroad.—Dr. Muhlenberg Kellar Knauff, Two Harbors; Dr. and Mrs. Arthur T. Mann, Minneapolis, and Dr. Olaf J. Hagen, Moorhead, have returned from abroad.

Personal.—Dr. John E. Crewe is acting at present as health officer of Rochester.—A banquet was tendered Dr. William E. Harwood, Eveleth, by his professional associates of the Range Medical Association, at Hibbing, September 4. Dr. Harwood is about to move to Peoria.

Cancer Committee Named.—Drs. Warren A. Dennis, St. Paul; William J. Mayo, Rochester, and James E. Moore, Minneapolis, the committee on cancer of the Minnesota Public Health Association have been invited to act as the Minnesota State Committee on Cancer for the American Society for the Prevention and Control of Cancer.

Selection of Sanatorium Site.—At a meeting of the commissioners of the Southwestern Minnesota Antituberculosis Sanatorium Association which includes the counties of Lincoln, Lyon, Pipestone, Murray, Cottonwood, Rock, Nobles and Jackson, held in Windom recently, it was decided to name a first, second and third choice of sites, leaving the final selection to the State Board of Control. The first choice is that offered by Windom on Fish Lake, about 4 miles east of Windom, 54 acres in extent, at \$110 an acre; the Currie site of 123 acres is located 100 miles north of Currie on the shores of Lake Shetek and is offered at \$150 an acre, and the site offered by Worthington is 1½ miles south of that place on the shores of Lake Okebena and consists of 60 acres offered at \$150 an acre. It is proposed to construct buildings costing about \$100,000.—The Wabasha County Tuberculosis Commission has selected Wabasha as the site for the State Sanatorium.

NEW YORK

District Society Meeting.—The Eighth District Branch Medical Society will hold its annual meeting at Niagara Falls, September 23 and 24, under the presidency of Dr. Arthur A. Bennett.

Medical Club Organized.—The Miamonides Club, a private medical club recently organized in Buffalo, held its first meeting at the Hotel Statler, recently, under the presidency of Dr. Marcell Hartwig.

Mallein Test Required on Imported Horses.—Beginning September 1, this state will not permit any horses to enter its borders unaccompanied by a certificate of freedom from glanders, established by the mallein test.

Personal.—Drs. Lucien Howe and Ray Johnson, Buffalo, have returned from abroad.—Drs. Lester Levyn and Milton H. Goldberg, Buffalo, are reported to be still in the war zone in Europe.—Dr. Abraham S. Tepper, house surgeon at St. Joseph's Hospital, Far Rockaway, Long Island, was operated on for appendicitis in the hospital, September 1, and is reported to be doing well.—Dr. Harold K. Faber, Westfield, has accepted a position on the staff of the Rockefeller Institute for Medical Research in New York City.

Epidemic Sore Throat in Rockville Centre.—In Rockville Centre, a town of 4,250 inhabitants, during the first half of June over 200 cases of septic sore throat developed. About 90 per cent. of the sick were found to have used milk from a single dairy. Altogether about 400 quarts were delivered daily from the dairy to about 173 customers. A milk supply making up one-fourth of the total was shown to be in use in at least nine-tenths of the cases. Over 200 cases occurred among 173 customers and about one case is recorded for every 2 quarts of milk delivered.

New York City

Personal.—Dr. Walter Booth Adams, Beirut, Syria, is spending a furlough of eight months in the United States.—Dr. William H. Luckett and Dr. and Mrs. George A. Tuttle, and Dr. Jacob L. Maybaum have returned from Europe.

Typhoid Fever in Brooklyn.—Typhoid fever has developed in the Park Slope section of Brooklyn since September 1, and up to September 10, twenty-nine cases have been reported. Vigorous search is being made to find the source of the infection.

Health Department Official Dies.—Mr. Alfred T. Metcalf, for twenty-eight years connected with the Health Department of Brooklyn and recently chief clerk, died in his summer cottage at Sheepshead Bay, September 2, from cerebral hemorrhage, aged 61.

For a Health Home.—The bulk of the estate of Jacob Langeloth, estimated at more than \$10,000,000, has been bequeathed as a foundation for a home, to be known as the Valeria*Recreative and Convalescent Home. The institution is designed as a home for people of refinement and education who cannot afford to pay the charges exacted at health resorts. It is to be non-sectarian.

The Death-Rate of Children Under 5 Years of Age.—A recent *Bulletin* of the Health Department states that the question is often asked "Why do all organizations direct their efforts to saving babies under 1 year of age only to allow them to die during the second or third year?" The department has therefore made an investigation of the death-rates of children at the various age periods under 5 years. A comparison of the five-year period from 1904 to 1908, previous to the establishment of the Bureau of Child Hygiene, with the five-year period from 1909 to 1913, shows that there has been a decrease in the death-rate of 23 per cent. in children under 1 year of age, of 25 per cent. between 1 and 2 years, 27 per cent. between 2 and 5 years, and a total of 26 per cent. under 5 years of age.

OHIO

In the War Zone.—Dr. and Mrs. James G. Grant, Akron, are on their way home from Europe by way of Denmark.—Dr. Martin Stamm, Fremont, is reported to be serving with the hospital corps of the Swiss army in Berne.—Dr. Miloslav Francisci, Cleveland, has returned from Europe.

Toledo Will Grade Restaurants.—In future every restaurant in Toledo will be graded by the City Board of Health. Cleanliness, absence of odors, personal hygiene of employees and equipment of kitchen will be taken into consideration. Each restaurant will be given a card with its grade, "A," "B," "C," marked thereon. Those below "C" will be barred.

District Tuberculosis Hospital.—Ashtabula, Geauga, Lake and Trumbull counties have been placed in Tuberculosis Hospital District No. 4, by the Division of Tuberculosis of the State Board of Health. Under the amended district hospital law, passed last winter, the cost of the erection and maintenance

nance of the hospital is assessed against each county in direct proportion to its tax duplicate.

To Urge Health Laws.—Dr. Benjamin R. McClellan of Xenia will be chairman, and George V. Sheridan of Columbus, secretary, of a committee of the Ohio State Medical Association, Ohio State Board of Health, Ohio State Dental Association, Ohio Commission for the Blind and Ohio State Pharmaceutical Association, to urge various changes in, and additions to, the health laws at the next session of the legislature.

Conference on Public Health.—The Ohio State Medical Association, the Ohio Society for the Prevention of Tuberculosis and the State Board of Health were represented at a conference on public health held in Columbus September 3. The conference discussed suggested legislation dealing with the division of the state into health districts, strengthening the act under which the commission for the blind operates, and amendments to the tuberculosis law providing for easier entrance to the Mount Vernon Tuberculosis Sanatorium.

Cincinnati

Abroad and Returned from Abroad.—Drs. William C. Herman, J. Henry Schroeder and son, Julien E. Benjamin and John M. Withrow have returned from abroad.—Dr. and Mrs. Adolf F. Morgenstern are reported to be in Koenigsberg.—Dr. and Mrs. William Gillespie are waiting in Edinburgh for an opportunity to return to this country.

Personal.—Dr. E. Gustave Zinke has been appointed a member of the Municipal Board of Health in place of Dr. Edward W. Walker, term expired.—Dr. Charles F. Sanborn has resigned as superintendent of the Cincinnati City Hospital, to take effect November 1.—It is stated in the daily *Press* that Dr. Arthur C. Bachmeyer is to succeed Dr. Sanborn as superintendent and that Dr. Walter E. List, at present assistant superintendent at the hospital, will be appointed superintendent of the Branch Hospital in place of Dr. Bachmeyer.—Dr. U. G. Senour, Pleasant Ridge, has been appointed district physician for Kennedy Heights.

PENNSYLVANIA

New Medical Club House.—Plans have been completed for the new club house at Wilkes-Barre, for the Luzerne County Medical Society. It is to be of stone and brick, 48 by 65 feet, fireproof and will cost \$20,000.

New Buildings for State Hospital.—At a meeting of the trustees of Rittersville State Hospital, plans were adopted for the erection of a reception building, two buildings for tuberculosis patients and a nurses' home and an isolation cottage.

Personal.—Dr. Henry J. Benz has succeeded Dr. Henry B. Burns as superintendent of the Bureau of Child Welfare of the Department of Health of Pittsburgh.—Dr. Adolph Koenig, Pittsburgh, has been reappointed a member of the State Bureau of Medical Registration and Licensure.—Dr. W. D. De Long, Reading, and J. Clayton Weidman, Mercer, have been reappointed members of the State Dental Board.—Dr. Henry B. Burns, retired superintendent of the Child Welfare Bureau of the Pittsburgh Department of Health, was given a dinner by the employees of the Bureau, August 31, and was presented with a traveling bag. Dr. Burns began his work as head of the Medical Department of the Board of Education of Pittsburgh.

Philadelphia

Hospital News.—Charity Hospital announces, in addition to the Roentgen-ray room, the remodeling of operating-room and alterations in different parts of the building. Alterations and additions are to be made to the Rush Hospital for Consumptives.—Ground has been broken for a four-story addition, 44 by 36 feet, to the Kensington Hospital, at a cost of \$19,000.—In order that colored orphans and deficients may receive vocational training under the most favorable conditions and that colored convalescents may be guaranteed a restoration of health, the authorities of the Mercy Hospital are planning to remove their social service department to the country. So soon as a desirable farm site can be found in Philadelphia County, buildings will be erected for one of the most complete, scientifically equipped institutions conducted by colored people in the United States.

WISCONSIN

European Travelers.—Dr. Urban J. Durner, Milwaukee; Dr. Charles W. Giesen, Superior, and Dr. William Webber Kelly, Green Bay, have returned from abroad.

Personal.—Dr. William F. Lorenz of the staff of the Mendota State Hospital for the Insane has returned after a six months' trip of research in the South, devoted to the study of the causes and effects of pellagra.—Dr. R. Jay Elliott, National Home, has been elected surgeon-general of the United Spanish War Veterans.

State Hygienic Laboratory Enlarged.—The entire top floor of south hall in the University of Wisconsin, Madison, has been given up to the state laboratory of hygiene which is maintained out of university funds and is under the supervision of a special committee composed of Dr. Cornelius A. Harper and William F. Whyte, representing the State Board of Health, and president, C. R. VanHise and Prof. Charles R. Bardeen, dean of the medical school representing the university. The laboratory is under the immediate charge of Dr. W. D. Stovall, chief bacteriologist, and E. J. Tully, chief chemist.

GENERAL

District Society Announcement.—The Iowa and Illinois District Medical Association announces through its program committee that at the regular fall meeting to be held the first week in October in Davenport, Dr. William J. Mayo and his guests will address the society, and that at the meeting to be held October 23 in Rock Island, Ill., Dr. Albert J. Ochsner, Chicago, will be the guest of the society.

Railway Surgeons Convene.—At the annual meeting of the Minneapolis, St. Paul and Sault Ste. Marie Railway Surgical Association held in St. Paul last week, the following officers were elected: president, Dr. Alexander J. McCannel, Minot, N. Dak.; vice-president, Dr. John B. Darling, St. Paul; secretary-treasurer (ex officio), Dr. John H. Rishmiller, Minneapolis. Minneapolis was selected as the next place of meeting.

Conference on Tuberculosis.—The second Mississippi Valley Conference on Tuberculosis, in cooperation with the National Association for the Study and Prevention of Tuberculosis, will be held in St. Louis, October 6 to 8. This is the first of four sectional conferences being held on tuberculosis, the others being at Bangor, Maine, Philadelphia and Atlanta. For information write to Mr. W. A. Jones, Jr., Mississippi Valley Conference on Tuberculosis, St. Louis, Mo.

Cumberland Valley Physicians Meet.—At the annual meeting of the Cumberland Valley Medical Association held at Boiling Springs Park, September 3, the following officers were elected: president, Dr. Charles M. McLaughlin, Greencastle, Pa.; Drs. S. Seibert Davis, Boonesboro, Md.; Samuel E. Mowery, Mechanicsburg, Pa., and John W. Croft, Waynesboro, Pa.; secretary, Dr. John J. Coffman, Scotland, Pa. (reelected); treasurer, Dr. Paul P. Allen, Chambersburg, Pa.

Colored Practitioners' Meeting.—The Tristate Association of colored physicians, dentists and pharmacists of Ohio, Kentucky and Indiana met in Indianapolis, September 7 to 9, and perfected an organization and elected the following officers: president, Dr. William A. Method, Columbus, Ohio; vice-president, Dr. William J. Woodlin, Columbus, Ohio; secretary, Dr. Henry W. Armistead, Indianapolis, Ind.; treasurer, Dr. Abram L. Cabell, Terre Haute, Ind. The next meeting of the association will be held in Columbus, Ohio, in July next.

A Warning.—A subscriber writes that a certain Donald McCormick is soliciting subscriptions to a bureau called the "American Bureau (or Institute) of Medical Research," at Indianapolis, Ind. The purpose of this bureau, he states, is to receive all medical journals of the world and to make reprints of each individual article which are kept in stock and lent to subscribers to the bureau. The cost of membership is \$5 a year. A physician in Iowa who addressed the bureau had his inquiry returned with the announcement that no such institution existed, and that the addressee was not at the place named.

Bequests and Donations.—The following bequests and donations have recently been announced:

Mt. Sinai Hospital, German Hospital and Manhattan Eye and Ear Hospital, each \$5,000; the Isabella Heimath and St. John's Home, New York City, each \$1,000 by the will of Jacob Langeloth.

Mt. Sinai Hospital, Montefiore Home, Lebanon Hospital and Beth Israel Hospital, New York City, each \$5,000 by the will of Renno Neuberger.

Montefiore Home, New York City, \$2,500 for endowment of a bed in memory of his parents, by the will of Albert Rich.

German Hospital, New York City, \$1,000 by the will of Adam Schulz.

St. Vincent's Hospital, New York City, \$2,307, the proceeds of a lawn fete.

Mt. Sinai Hospital, \$5,000, and the New York Institute for the Instruction of Deaf and Dumb, New York City, one-half of the residue of the estate up to \$5,000, by the will of Moses Weinstein.

Children's Hospital, Boston Floating Hospital and Hospital Cottages at Baldwinville, Mass., each \$500 by the will of Francis F. Sears.

Mercy Hospital, Chicago, \$250,000 by the will of Charles Heines, St. Charles, Ill.

FOREIGN NEWS

Postponement of Pan-American Student Congress.—Business and finance are so demoralized in South America by the war in Europe that the Chilean minister at Washington has been officially notified that the international Pan-American congress of university students will not be held as announced at Santiago, in September, and is indefinitely postponed. A press dispatch states that three delegates from the United States are already on their way to Chili. The scope of the meeting was mentioned in these columns recently, page 696.

The Propaganda in Germany.—The recent annual representative assembly of the organized medical profession in Germany—the so-called Aerztetag—adopted a resolution to increase the dues a trifle in order to raise a fund of about \$6,200 annually to be expended in fighting quackery and nostrums. Part of the sum, also, is to be given to further the efforts of the German Council on Pharmacy and Chemistry. An editorial in the *Therap. Monatshefte* comments on this action of the Aerztetag as of far-reaching import, saying that such a decided practical measure taken by the profession itself to combat medical frauds cannot fail to exert an influence on the authorities above and on the rank and file of the profession below, and produce more of an effect than any amount of appeals to legislative factors.

Deaths in the Profession Abroad.—Dr. Gutierrez, count of San Diego, senator, director of the Instituto Rubio and a leading practitioner at Madrid, aged 63.—Dr. G. Vianna, assistant at the Oswaldo Cruz Institute for Infectious Diseases at Rio de Janeiro and author of the successful method of treating infection with species of *Leishmania* by intravenous injection of tartar emetic, has succumbed to infection professionally acquired, aged 30.—Surgeon-General Sir Anthony Dickson Home, V.C., K.C.B., probably the most distinguished officer on the retired list of the Royal Army Medical Corps; died in London, August 9, aged 87. He entered the medical corps in 1848 and served in the Crimean War and during the Indian Mutiny where he won the Victoria Cross by his heroic defense of the wounded left behind at Lucknow by the relieving column of Havelock. After this he served through the China, Maori and Ashantee campaigns and in 1880 was made surgeon-general and appointed Principal Medical Officer of Her Majesty's Forces in India. He was retired in 1886.—A. E. Cordes, a leading obstetrician and gynecologist connected with the university of Geneva, Switzerland, aged 69. He was a frequent writer of articles on his specialty, not only in French, but in British medical journals, and was one of the delegates to the international medical congress held in Washington in 1887 and secretary of the international congress on gynecology and obstetrics which met at Geneva in 1896.—Alfred Hegar, professor of obstetrics and gynecology at Freiburg i. B. until 1904, aged 84. Almost the last article from Hegar's pen was reviewed in *THE JOURNAL*, Nov. 8, 1913, warning that the catheter should never be used in examining the uterus, even when a pregnancy seems wildly improbable; he was discussing the lessons to be learned from the Niebergall case. He founded the *Beiträge zur Geburtshilfe und Gynaekologie*, now in its nineteenth volume.

CANADA

Personal.—Prof. Irving Heward Cameron has returned to Toronto.—Dr. William Grant Stewart, Montreal, and Dr. Maxwell Luterman, Montreal, have returned from Europe.—Dr. H. C. Wetmore, St. John, N. B., has been appointed deputy receiver-general at the port of St. John, N. B.

Toronto's Health.—Dr. Charles J. Hastings, municipal officer of health, has reported to the local board of health that during the past five years the death-rate in Toronto per 1,000 of population has decreased approximately 25 per cent. In August the total deaths were fourteen less than in August of last year. During the first eight months of the present year there were 421 fewer deaths than in the corresponding period of the past year. Owing to the establishment of the Child Welfare Department, there has been a marked decrease in infant mortality.

WAR NOTES

Medicine Embargo Raised.—The Russian government has authorized the Red Cross Society to import drugs and surgical instruments free of duty during the war.

Roentgen Returns Decoration.—Berlin papers state that Professor Roentgen has given back the gold medal presented him by the Royal Society in honor of his discovery, the reason assigned being the attitude of England in this war.

Red Cross Funds to Serbia.—The president of the Serb-American Red Cross Committee has sent by cable \$20,000 to the Red Cross Committee in Serbia, and also \$10,000 collected by the Serb-American Alliance of California. This money is being transmitted by way of Greece.

Hospital Unit Offered to Canada.—Dr. Kendall, secretary of the Edinburgh University Club of New York, has offered a hospital unit to the Canadian government composed of graduates of the university in the United States, the unit to be fitted out and equipped by its own members.

American Women's Hospital in London.—The American Women's Hospital in London, with accommodation for 200 patients and fully equipped through the efforts of American women in London, has been turned over to the War Office and is housing a large number of wounded soldiers.

Red Cross Surgeons Expect Call.—Surgeons available for Red Cross work and who have indicated their willingness for duty have been advised by the relief board to hold themselves in readiness for a call to duty at any time. A similar notice has been sent to the 5,000 Red Cross nurses registered in the United States.

Emigrant Station Turned Over to Red Cross.—The North German Lloyd Emigrant Railway Station at Bremen, which was completed in April last, has been turned over to the Red Cross for hospital purposes, and the package room of the station has been set apart as a depository for articles of food and clothing to be distributed by the Red Cross to the soldiers.

Daughters of Empire Equip Hospital.—Dr. Donald Armour and Sir William Osler are to have charge of the Queen's Canadian Military Hospital to be established in London, England, with the money raised by the Imperial Daughters of the Empire in Canada. Dr. Philippe Pelletier, agent-general for the province of Quebec in England, has been appointed a member of the medical staff of this hospital.

To Safeguard Soldiers' Health.—The specific request from the minister of militia for the services of Toronto's bacteriologist, Dr. George G. Nasmith, has been assented to by the Toronto Board of Health. Dr. Nasmith will, therefore, go to Europe with the first Canadian contingent to see that the soldiers have a good water-supply and to advise on all matters of sanitation.

No Dum-Dum Bullets.—French medical officers who were captured by the Germans at Namur and are on their way back to France by way of England, are said to have reported that they saw no evidence of soldiers having been wounded by dum-dum bullets on either side. The medical service of the Germans and allies was said to be excellent, but it was noted that the German wounded were often discharged too early from the hospitals.

The American Hospital.—The American Hospital which is housed in the Lycee Pasteur at Neuilly received its first lot of wounded, September 5. On the first sound of firing, the ambulances of this hospital dashed to the front, picked up the wounded and returned them rapidly to Neuilly. About fifty patients were accommodated at this time. An appeal has been made by prominent women of New York for \$250,000 for the hospital so that it may be able to provide 1,000 beds for wounded soldiers.

Our Austrian Exchanges.—The Vienna exchanges of *THE JOURNAL* arrive irregularly and with comparatively few pages, but the Association of Medical Publishers announce that they will make every effort to keep issuing their publications regularly, although in these troublous times it will not be possible to issue the medical periodicals in their complete form. They add that the lack of articles to publish would prevent this any way. Delays in distribution and transmission will be inevitable.

Red Cross Expedition Sails.—The American National Red Cross steamer, *Red Cross*, whose approaching departure was noted in last week's issue of *THE JOURNAL*, left her anchorage in Gravesend Bay, September 13. The delay in sailing was due to fear of international complications over

the make-up of the crew. In addition to the thirty surgeons and 125 trained nurses on the *Red Cross*, she carries a cargo of thousands of pounds of absorbent cotton, bandages, drugs and surgical instruments. Her first stop will be at Falmouth, England, where twenty-four nurses and six surgeons will be landed. She then proceeds to Rotterdam, where surgeons and nurses for Austria, Germany and Russia will disembark, and the balance will be taken to some French port, probably Cherbourg.

The Potassium Supply.—On another page mention is made of shortage of potassium compounds due to the interruption of commercial intercourse with Germany. Although the German monopoly of the market for potassium compounds is practically complete, commercial possibilities of potash exist in other countries. There are said to be resources in Spain, which, however, are undeveloped and likely to remain so for some time. After numerous false rumors it appears that a source of potash supply in this country is really about to be developed. The Secretary of the Interior has recently announced that within the next three months American potash would be produced at Searles Lake, Cal. The maximum production of the plant is expected to be between 37,000 and 38,000 tons a year. The amount of German potash annually imported is estimated to exceed 230,000 tons, so that this source of domestic supply will not of itself meet the demands of the country. Economy will still be necessary with reference to potassium compounds.

PARIS LETTER

PARIS, Sept. 4, 1914.

The War

The seriousness of the political events which have occurred since my last letter have drawn universal attention to the war. As a matter of course, medical life has also felt the effects of the great European conflagration. The readers of *THE JOURNAL* will therefore pardon me if my present letter is devoted altogether to matters connected with the war.

Patriotic Devotion of the Medical Profession

A large number of physicians with no military connection have offered their services to the war department. Especially notable is the case of Dr. Darroze, who took part in the campaign of 1870 as a physician and who to-day aged 68, has gone to the front, resuming the position that he occupied forty-four years ago. The army is at present well supplied with physicians. A detachment of the French *Red Cross*, composed of sixteen physicians, has set out for Serbia.

The services of the *Assistance Publique*, having been reduced by mobilization, have already been completely reorganized. On the other hand, some sections of the country being completely deprived of physicians by the mobilization, it is recommended that physicians who have no military obligations, and who are able to leave their customary residences, should inform the director of the sanitary service of the army corps in their vicinity, who will dispose of their services according to the needs that may arise.

Resources of the French Red Cross

The French *Red Cross* is composed of three societies, the *Société de secours aux blessés*, the *Association des Dames françaises* and the *Union des Femmes de France*. The first of these societies can put at the disposal of the war department 260 auxiliary hospitals with 17,000 beds; the second has 160 auxiliary hospitals with about 6,000 beds; the third has 180 auxiliary hospitals with 12,000 beds; altogether 600 auxiliary hospitals provided with about 35,000 beds and a staff ready to act. Moreover, each one of these societies receives fresh offers of assistance every day. The supplementary nurses, who are already offering their services in great number, will make it possible to open supplementary hospitals in many private buildings already placed at the disposal of the *Red Cross* as well as in college and other educational buildings. The *Union des Femmes de France* has organized sixty flying detachments each composed of a head nurse and six nurses under her, ready to leave for the front or for the military hospitals. The 10,000 nurses that the union has trained, many of whom have already had experience in Morocco, are prepared to start.

Advice to Surgeons with Regard to Wounds in War

August 10, Dr. Edmond Delorme, inspector general of the military health service, read a paper on this subject before the *Académie des Sciences* in which he emphasized the fact that at present military surgery ought to be conservative in

almost all cases, especially of bullet wounds. The small caliber of the wounds made by the bullets now used, the fact that the practice now is to refrain from probing the wounds, and the antiseptic and aseptic methods in use, have transformed the prognosis of most military wounds, have lessened complications and losses and have improved the results. The surgeon, therefore, ought to strive to cure, leaving the fewest possible ill effects. The methods of military surgery at the front necessarily differ from ordinary surgery, but in the hospitals at the rear they approach those of ordinary surgery.

Dr. Delorme reviewed successively the treatment of wounds of the soft parts produced by the pointed German bullet—wounds which are generally very narrow, not soiled with fragments of clothing and which are cured in a few days or weeks; treatment of wounds produced by the round ball of shrapnel and the treatment of fractures. For the latter conservation ought to be the rule. It insures recovery in the vast majority of cases, no matter what the bone affected or what the extent of the degree of comminution of the fracture. In abdominal wounds with intestinal lesions, though there may be room for argument as to the advisability of immediate laparotomy in ordinary surgery, it is altogether inadvisable in military surgery. The most recent wars, those in the Transvaal, Manchuria and the Balkans, have shown the harmfulness of laparotomy. In the Transvaal, laparotomy, though practiced by eminent surgeons, under most favorable conditions, gave fewer recoveries than did non-operative treatment.

The German bullet makes a small orifice in entering the abdomen and carries with it no infecting substance from the clothing. In the intestinal loops it makes only the smallest perforations which tend to close spontaneously. For such injuries the old treatment seems sufficient, namely, absolute rest, the patient not being transported to any distance, and complete abstinence from food and drink, especially the latter, for several days. This régime is rendered endurable by constantly rinsing out the mouth, employing rectal or subcutaneous injections of artificial serum with opium and keeping the patient in Fowler's position.

When, on the other hand, the speed of the projectile has been greater, when the bullet has ricocheted or when in case of the large shrapnel ball, the orifice of entry is larger, the intestinal wound or wounds are also larger and less apt to close spontaneously. Also the introduction of shreds of clothing is frequent. In such cases peritoneal infection is certain. The proper treatment is, in addition to measures already indicated, the use of the drop method of proctoclysis; the abdomen is opened rapidly and cleansed with ether after Morestin's method (*THE JOURNAL*, June 21, 1913, p. 1971) and drainage instituted.

Dr. Delorme emphasizes especially the fact that this operation is no longer the complicated procedure of classic laparotomy, which a staff of trained surgeons cannot perform more than three or four times a day while neglecting other wounded men, a fatiguing operation, increasing shock, liable to destroy reparative adhesions, demanding special surroundings and minute aseptic precautions in order that it may not give fewer recoveries than non-operative treatment. It is, on the other hand, a very simple, rapid procedure, within the ability of any practitioner. The *Académie des Sciences* has decided to suggest to the war department that Dr. Delorme's paper be printed for distribution to all the military physicians and surgeons of our army.

The Academy of Medicine and the War

The *Académie de médecine* has decided unanimously that all its members would place themselves at the disposal of the government for any purpose for which they may be useful to the country. It has asked to be given the necessary animals and apparatus for manufacturing small-pox vaccine. In view of the possible danger of small-pox epidemics, so common during war, the academy believes that not only children ought to be vaccinated, but all persons who have not been vaccinated within seven years. Instructions have been issued to the director of primary instruction and to the medical inspectors of schools to have all children attending the public and private schools revaccinated as soon as possible. Instructions have also been given to the general administration of the *Assistance Publique* (public charities) to have every applicant for help vaccinated or revaccinated.

In view of the possible danger of the spread of typhoid, the *Académie de médecine* has drawn the attention of the interior department to the opportunity for antityphoid vaccination, suggesting that such vaccinations be accomplished as soon as possible.

The Academy of Sciences and the War

In view of the serious situation of the country, the Académie des sciences has decided, as suggested by its president, Professor Appell, dean of the Faculté des sciences, to place itself at the disposal of the national defense. This resolution having been communicated to the government, some of the members were immediately placed, respectively, on commissions on the subjects of wireless telegraphy, aviation, explosives, hygiene and medicine.

The Jean-Jacques Berger prize having been awarded by the five academies of the institute successively to the most meritorious work affecting the city of Paris, was turned over by the Académie des sciences to the marquis de Vogüé, president of the Red Cross, for the military hospital of the institute at the hôtel Thiers.

Prohibition of Absinthe

The prefect of police of Paris forbade the sale of absinthe during the first days of mobilization. The Académie de médecine unanimously voted its congratulations to the prefect of police for this measure. Some of the prefects of the departments promulgated the same rule. At last the sale of absinthe, either to be consumed on the spot or in bottles to be carried away, has been forbidden by order of the minister of the interior throughout all France.

An American Organization

A Franco-American committee has been formed to assist in protecting from the horrors of war the children and young girls in the zone of operations. It will give its aid to such organizations as appear to be able to give the best care to such children and young girls during the war. It will reserve the right of advice and control in the name of its subscribers. The bureau of the committee is the following organization: president, Mrs. Cooper Hewitt; vice-president, Mrs. Robert Bliss; secretary, M. Auguste F. Jaccaci; treasurer, Mr. Frederic R. Coudert. Subscriptions may be addressed to MM. Coudert frères, boulevard Haussmann, 39, Paris, and Coudert Brothers, 2 Rector Street, New York.

The Offer of the Deaf-Mutes

M. Tournade, deputy of the Seine, has sent to the minister of war a letter in which deaf-mutes demand the honor of being utilized for the national defense. They explain that their infirmity is more apparent than real. Most of them are well built, healthy and strong and accustomed to take part in sports and gymnastics. There have formerly been deaf-mute soldiers, some of them volunteers; many of them are excellent shots, sight being more necessary for this than hearing. It is thought, however, that they may be better utilized for military purposes in the capacity of cyclists for carrying secret messages, as members of the ambulance corps, or in the auxiliary services in the national factories of arms and ammunition (where some of them are already employed) or in the national printing establishment, where others are also employed to fill the vacancies caused by mobilization.

War and the Medical Journals

On the fourth day of mobilization, the *Semaine Médicale* informed its subscribers that publication was indefinitely suspended. The *Presse Médicale*, though unable to continue to appear in its regular form, has been continued as a sheet of medico-military information.

Personal

Dr. Augagneur, formerly professor of the Faculté de médecine de Lyon, whose appointment as minister of public instruction I have already mentioned (THE JOURNAL, Aug. 1, 1914, page 415), has just vacated this position, having been appointed minister of the marine.

BERLIN LETTER

BERLIN, Aug. 22, 1914.

Personal

August 6, Alfred Hegar, a prominent German gynecologist, died at the age of 84. Hegar may be regarded as the founder of modern gynecology, especially of operative gynecology. In 1864, he was called to Freiburg as the successor of Professor Spiegelberg, without having previously held a university position. At this place he was for forty years the regular professor and director of the gynecologic clinic. His scientific works extend over the entire field of gynecology. A number of his treatises have a close relation to psychology

and social medicine. His principal work is the text-book of operative gynecology which he wrote in conjunction with his pupil, Kaltenbach. A number of years ago, in spite of his advanced age, he founded a journal entitled *Beiträge zur Geburtshilfe und Gynäkologie*, which contributed markedly to his reputation.

The War

Since the numerous bloody encounters, the activity of the surgeons has already begun. Under the specially favorable conditions of transportation, the effort will prevail, I believe, to treat the wounded not in the field hospitals but, so far as possible, to convey them in the hospital trains to their homes where they can doubtless be better cared for in the roomy and orderly regular hospitals. Already hospital trains carrying wounded have reached Stuttgart, Frankfurt and even Berlin. There are plenty of surgeons ready for their treatment. In the general enthusiasm, helpfulness and readiness for self-sacrifice which possess the entire German people in a remarkable way, physicians, as a matter of course have not remained the hindmost. Physicians to a far greater extent than necessity demanded have voluntarily offered themselves for the army in the field as well as for service in the hospitals. To be sure, gradually every force which is available may be demanded because in battles between armies numbering millions, the number of wounded will be enormous provided that peace is not concluded sooner than one can dare to hope for. In our army, evidence of whose brilliant organization is shown on all sides in the wonderfully rapid and smooth mobilization, the army medical service is certainly not in the lowest place and one may be sure that it will be completely equal to the task. Unfortunately, already some army surgeons have fallen on the battle-field. Naturally also, the sons of many physicians have already fallen. For instance, a son of Erb, the Heidelberg clinician, as well as the son of Surgeon-General Scheibe, formerly medical director of the Charité.

Since a large part of the civilian physicians who have gone into military service are not familiar with military surgery and military service in general, courses of instruction by active army surgeons will be held in all university towns, especially in Berlin, for the voluntary army surgeons.

Marriages

OSWALD SWINNEY LOWSLEY, M.D., Santa Barbara, Cal., to Miss Katherine V. Staples of Troy, N. Y., at Round Lake, N. Y., August 20.

LEONARD FORREST WOODWORTH, M.D., to Miss Bertha Victoria Fickling, both of LeSueur Center, Minn., September 8.

SOLON WASHINGTON CORNISH, M.D., Everett, Mass., to Miss Beatrice Melbourn Hosking of Chelsea, Mass., September 7.

ARTHUR MONROE CALVERT, M.D., Chicago, to Miss Anna May Gorby of Cave City, Ky., at Indianapolis, September 5.

THOMAS PATRICK HENNELLY, M.D., Pittsfield, Mass., to Miss Helena E. Wickham of South Lee, Mass., August 11.

JOHN CAMPBELL MORFIT, M.D., St. Louis, to Miss Sallie Hockaday Van Deventer of Mexico, Mo., September 1.

DANA FRANK CUMMINGS, M.D., Cherryfield, Maine, to Mrs. Blanche R. Day of Rockland, Mass., September 1.

NORMAN MARSHALL SMITH, M.D., to Miss May Louise Durst, both of Minneapolis, Minn., September 2.

HARRY STARK HOLMES, M.D., Glendive, Mont., to Miss Leota Robinson of Forsyth, Mont., August 29.

HOWARD NORTON FLEXER, M.D., Lakeview, Mich., to Miss Irene E. Singer of Sycamore, Ill., August 24.

EARL H. SNAVELY, M.D., Cedar Grove, N. J., to Miss Elizabeth C. McMahon at Newark, N. J., June 25.

LAWRENCE JEUS KAASA, M.D., to Miss Julia Olivia Thompson, both of Lake Mills, Iowa, September 2.

ARCHIBALD CARY LEWIS, M.D., to Miss Ruth D. Hatton, both of Memphis, Tenn., about June 2.

LEON BRAYTON HARRIS, M.D., to Miss Rosemary Laveck, both of Saginaw, Mich., September 7.

OSWALD PATRICK GOODALL, M.D., to Miss Harriet Blake, both of Los Angeles, September 1.

JAMES R. HARVEY, M.D., Footville, Wis., to Miss Helen Langdon of Chicago, August 26.

Deaths

Martin Hayward Post, M.D. Washington University, St. Louis, 1877; a prominent oculist of St. Louis; a Fellow of the American Medical Association and a member and once president of the American Ophthalmological Society; a member of the staff of St. Luke's Hospital, St. Louis Protestant Hospital, Missouri Baptist Sanitarium and ophthalmic surgeon to the Missouri School for the Blind; who went to Castle Park, Mich., in the middle of the summer to recuperate after an attack of pneumonia; died in Castle Park, September 2, from heart disease, aged 63.

George F. Jenkins, M.D. Missouri Medical College, St. Louis, 1867; a Fellow of the American Medical Association and fourth vice-president in 1903-1904; twice president of the Keokuk Medical Society and president of the Iowa State Medical Society in 1891; president and professor of principles and practice of medicine and clinical medicine, and physiology in Keokuk Medical College; chief of staff of St. Joseph's Hospital; eminent as a teacher and practitioner and universally beloved; died in St. Joseph's Hospital, Keokuk, September 4, aged 72.

Alexander Shirley Levery, M.D. College of Physicians and Surgeons in the City of New York, 1890; clinical instructor in medicine in Cornell University Medical College; a member of the New York Neurological Society; visiting physician to St. Luke's Hospital; died suddenly in his apartment in New York City, about August 28, from cerebral hemorrhage, aged 48.

Joseph S. Sutphen, M.D. New York University, New York City, 1865; for nearly half a century a practitioner of Newark, N. J., and for many years physician to the Essex County prison; from 1878 to 1880 a member of the Board of Freeholders, and in 1891 a member of the Board of Education of Newark; died at the home of his sister in that city, August 20, aged 74.

William Freeman Nye, M.D. Northwestern University Medical School, 1878; for nearly forty years a practitioner of Minneapolis; a Fellow of the American Medical Association; for four years a member of the board of aldermen and for several years deputy coroner of Hennepin County; died at the home of his daughter at Mound, Lake Minnetonka, Minn., August 30, aged 63.

William Lofland Dudley, M.D. Miami Medical College, Cincinnati, 1885; of Nashville, Tenn.; formerly dean of Vanderbilt University, Nashville, Tenn.; once president of the Southern Intercollegiate Athletic Association and known as the "father of Southern athletics"; died September 8, on a train near Clifton Springs, Mich., from cerebral hemorrhage, aged 55.

Enoch Wood Keegan, M.D. Rush Medical College, 1861; surgeon in the Federal service during the Civil War; for more than half a century a practitioner of Crawfordsville, Ind.; a member of the city council and for one term coroner of Montgomery County; died at his home in Crawfordsville, August 29, from cerebral hemorrhage, aged 78.

Milton M. Walker, M.D. University of Maryland, Baltimore, 1867; a charter member of the Medical Society of Virginia, and corresponding secretary of the society from 1880 to 1882; a Confederate veteran and also surgeon of U. S. Volunteers during the Spanish-American War; died at his home in Oldhams, Va., June 27, aged 71.

William C. Gouinlock, M.D. College of Physicians and Surgeons in the City of New York, 1865; University of Toronto, Ont., 1879; for more than thirty years a resident of Warsaw, N. Y., and identified with the salt industry of that place; died in the Warsaw Hospital, August 30, after an operation for disease of the intestine, aged about 70.

Joseph Henry Byrne, M.D. College of Physicians and Surgeons in the City of New York, 1885; of New York City; a Fellow of the American Medical Association and the New York Academy of Medicine; died suddenly from heart disease in New York City, August 27, aged 49.

Helen DeWitt Justin, M.D. Woman's Medical College of the New York Infirmary for Women and Children, New York City, 1879; of Castle, N. Y.; a member of the Medical Society of the State of New York; died in Rochester, Minn., July 19.

Thomas B. Owings, M.D. University of Maryland, Baltimore, 1852; died at his home in Ellicott City, Md., August 28, from senile debility, aged 84.

Alexander Hazard, M.D. University of Pennsylvania, Philadelphia, 1867; a medical cadet during the Civil War; formerly a practitioner of Ouray, Colo., and later a resident of Philadelphia; died at his summer home in Atlantic City, N. J., August 25, aged 67.

Richard P. Walker, M.D. Kansas City (Mo.) Medical College, 1883; Jefferson Medical College, 1855; a member of the Missouri State Medical Association; died at his home in Belton, Mo., August 26, from cerebral hemorrhage, aged 54.

Alexander Hunter, M.D. University of Colorado, Boulder, 1894; University and Bellevue Hospital Medical College, 1899; local surgeon for the Northern Pacific Railroad at Coeur d'Alene, Idaho; died at his home in that city, August 7, aged 47.

Samuel R. Bird, M.D. University of Pennsylvania, Philadelphia, 1853; formerly a member of the Maryland House of Delegates from Calvert County and later in the customs service; died at his home in Baltimore, August 17, aged 86.

Levi D. Sheets, M.D. New York University, New York City, 1849; surgeon with the cavalry division of the Second Army Corps during the Civil War; died at his home in Glen Ridge, N. J., August 24, aged 88.

William D. Flack, M.D. Northwestern University Medical School, Chicago, 1912; of Farmington, Ill.; died in Wesley Hospital, Chicago, August 26, from meningitis following a mastoid operation, aged 31.

Dudley Leavitt, M.D. College of Physicians and Surgeons in the City of New York, 1890; of West Stockbridge, Mass.; died in a hospital in Pittsfield, Mass., August 23, from malignant disease, aged 50.

William L. Gaboury, M.D. Queens University, Kingston, Ont., 1912; of Pembroke, Ont.; while driving across a railroad track recently, was struck by a train and instantly killed, aged 25.

Henry Greggs Farish, M.D. University of Pennsylvania, Philadelphia, 1849; for sixty-four years a resident of Liverpool, N. S.; died at his home in that place, June 30, aged 88.

Elwin H. Damon, M.D. Cleveland University of Medicine and Surgery, 1878; of Rittman, Ohio; died in a hospital in Cleveland, August 20, after a surgical operation, aged 63.

James Henry Sanderson, M.D. College of Physicians and Surgeons in the City of New York, 1890; died at his home in Worcester, Mass., August 28, from pneumonia, aged 47.

James Bruce Coleridge, M.D. Trinity Medical College, Toronto, Ont., 1901; three times mayor of Ingersoll, Ont.; died at his home, July 7, from nephritis, aged 35.

Samuel D. Griffith, M.D. Starling Medical College, Columbus, Ohio, 1886; of Columbus; died at the home of his brother in Worthington, Ohio, August 19, aged 53.

John N. Wilkins, M.D. National Medical University, Chicago, 1896; formerly of Chicago; died at the home of his daughter in Oakland, Cal.; recently, aged 83.

Frederick Parker, M.D. Trinity Medical College, Toronto, Ont., 1895; of Stratford, Ont.; died suddenly in his automobile, July 11, from heart disease, aged 50.

Arthur Watson Grover, M.D. Western University, London, Ont., 1907; formerly of Brandon, Man.; died at his home in Dresden, Ont., June 28.

Stephen H. Cloyd, M.D. Eclectic Medical Institute, Cincinnati, 1887; died at his home in West Alexandria, Ohio, July 29, aged 53.

Henry Walmsley Welch, M.D. Trinity Medical College, Toronto, 1890; of Okotoks, Alta.; died in Calgary, Alta., July 7, aged 48.

Addison Alexander Armstrong, M.D. University of Michigan, Ann Arbor, 1883; died at his home in Athens, Pa., June 10, aged 55.

Robert Boyd, M.D. Barnes Medical College, St. Louis, 1897; died at his home in Weatherford, Texas, July 10, aged 45.

Almena Jane Baker Flint, M.D. Boston University School of Medicine, 1876; died recently in her apartment in Boston.

John W. Bronaugh, M.D. Washington University, St. Louis, 1861; died at his home in Mounds, Okla., August 6, aged 80.

Charles Edward Winslow, M.D. Rush Medical College, 1882; died at his home in Monrovia, Cal., June 19, aged 59.

Arthur Vaillancourt, M.D. Laval University, Quebec, 1899; died at his home in Waterloo, Que., July 2, aged 38.

The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION

PATENT MEDICINES IN GREAT BRITAIN

The Report of the Select Committee on "Patent Medicines" with Its Findings and Recommendations

More than two years ago the British government appointed a Select Committee on Patent Medicines to investigate the nostrum evil in that country. THE JOURNAL has, from time to time, called attention to the fraudulence of the "patent medicine" business across the water, and has emphasized the fact that Great Britain is some years behind the United States in attempting to curb one of the greatest evils that menace the public health. Long after the Food and Drugs Act brought about a certain moderation in claims on the labels of American "patent medicines" as sold in this country, the same nostrums were sold in Great Britain under claims that obtained in this country in pre "pure-food-law" days. In other words, the nostrum labels on the British market contained the same false and fraudulent claims that characterized the labels of the same product in this country before the passage of the Food and Drugs Act.

These facts were brought out in detail in the article, "American and British Labels," that appeared in this department in THE JOURNAL for July 20, 1912. At about the same time a series of educational charts dealing with "patent medicines" and quackery were prepared by the Propaganda Department for the American Medical Association's exhibit at the Fifteenth International Congress on Hygiene and Demography. Some of these charts called attention specifically to the difference in the claims made for the same product on American and British labels, respectively. During the summer of 1912 the British embassy through the British consulate at Philadelphia, requested the American Medical Association to furnish the Select Committee with such data as it had on the subject of "patent medicines" and quackery. A full set of the literature prepared in the Propaganda Department was forwarded, together with some of the educational charts that dealt specifically with the difference in labeling of "patent medicines" in Great Britain and the United States, respectively.

The hearings before the Select Committee were exceedingly interesting and brought out many facts long known to those who had investigated the subject, but little appreciated by the general public. Some of these have been referred to at different times in THE JOURNAL. Those of our readers who are interested in the propaganda against fraud in medicine will appreciate the value of the report that has recently been presented by the Select Committee on "patent medicines," whose findings and recommendations we quote in full.

THE FINDINGS OF THE COMMITTEE

After carefully considering the evidence that was laid before it the committee reported its findings as follows:

"1. That there is a large and increasing sale in this country of patent and proprietary remedies and appliances, and of medicated wines.

"2. That these remedies are of widely differing characters, comprising (a) genuine scientific preparations; (b) unobjectionable remedies for simple ailments, and (c) many secret remedies making grossly exaggerated claims of efficacy, causing injury by leading sick persons to delay in securing medical treatment, containing in disguise large proportions of alcohol; sold for improper purposes; professing to cure diseases incurable by medication; or essentially and deliberately fraudulent.

"3. That this last-mentioned class (c) of remedies contains none which spring from therapeutical or medical knowledge, but that they are put on the market by ignorant persons, and in many cases by cunning swindlers, who exploit for their own profit the apparently invincible credulity of the public.

"4. That this constitutes a grave and widespread public evil.

"5. That in British Dominions and foreign countries severe legal restrictions exist, and that there is a tendency still further to strengthen the law against these articles.

"6. That no department of state and no public officer is charged with the duty of controlling the sale and advertisement of proprietary remedies in this country; that the home office and the local government board are virtually powerless in this respect; that the privy council office, though supposed to be specially concerned with the sale of drugs, has no initiative in the matter, and, in fact, it fulfils no useful function in this connection.

"7. That the existing law is chaotic and has proved inoperative, and that successful prosecution for fraud in the advertisement and sale of secret remedies is fraught with the greatest difficulty, though the public prosecutor has perhaps not sufficiently tested the powers of the existing law in respect to such cases.

"8. That consequently the traffic in secret remedies, except as regards scheduled poisons and the grosser forms of impropriety, is practically uncontrolled in this country.

"9. That this is an intolerable state of things, and that new legislation to deal with it rather than merely the amendment of existing laws is urgently needed in the public interest.

"10. That grave injury is caused to the public by the existing large sale of medicated wines.

"11. And that while, for reasons already given, it is not desirable to require the exhibition of formulas of every secret remedy, nevertheless it is improper that under the protection of the law enormous quantities of alleged remedies should be sold the composition of which is unknown to any person except the manufacturers of them; and that, therefore, the formulas of all secret remedies should be required to be communicated to a competent officer appointed under the authority of a minister of state, but that such formulas should not be divulged to any other person except as hereinafter recommended."

THE RECOMMENDATIONS OF THE COMMITTEE

The committee therefore recommends:

"1. That the administration of the law governing the advertisement and sale of patent, secret and proprietary medicines and appliances be coordinated and combined under the authority of one department of state.

"2. That this administration be part of the functions of the ministry of public health when such a department is created, and that in the meanwhile it be undertaken by the local government board.

"3. That a competent officer be appointed to this department, with the duty of advising the minister at the head of the department concerned regarding the enforcement of the law in respect of these remedies.

"5. That there be established at the department concerned a register of manufacturers, proprietors and importers of patent, secret and proprietary remedies, and that every such person be required to apply for a certificate of registration and to furnish (a) the principal address of the responsible manufacturer or representative in this country, and (b) a list of the medicine or medicines proposed to be made or imported.

"6. That an exact and complete statement of the ingredients and the proportions of the same of every patent, secret and proprietary remedy; of the contents other than wine, and the alcoholic strength of every medicated wine, and a full statement of the therapeutic claims made or to be made; and a specimen of every appliance for the cure of ailments other than recognized surgical appliances be furnished to this department, such information not to be disclosed except as hereinafter recommended, the department to control such statement, at their discretion, by analyses made confidentially by the government chemist.

"7. That a special court or commission be constituted with power to permit or to prohibit in the public interest, or on the ground of non-compliance with the law, the sale and advertisement of any patent, secret or proprietary remedy or appliance, and that the commission appointed for the purpose be a judicial authority, such as a metropolitan police magistrate sitting with two assessors, one appointed by the department and the other by some such body as the London Chamber of Commerce.

"8. That the president of the local government board (or minister of health) have power to institute the necessary

proceedings to enforce compliance with the law, the sale and advertisement of any patent, secret or proprietary remedy or appliance.

"9. That a registration number be assigned to every remedy permitted to be sold, and that every bottle or package of it be required to bear the imprint 'R.N. . . .' (with the number), and that no other words referring to the registration be permitted.

"10. That in the case of a remedy the sale of which is prohibited the proprietor or manufacturer be entitled to appeal to the high court against the prohibition.

"11. That the Department be empowered to require the name and proportion of any poisonous or potent drug forming an ingredient of any remedy to be exhibited on the label.

"12. That inspectors be placed at the disposal of the department to examine advertisements and observe the sale of proprietary remedies and appliances.

"13. That an annual fee be payable in respect of every registration number issued."

Believing that some of the existing laws could be so amended as to give greater protection to the public, the committee recommended:

"1. That the Stamp Acts be consolidated and amended to remove the numerous existing anomalies and unreasonable exceptions. In this connection pure drugs vended entire under a fancy name should no longer be exempt from duty; the distinction between the name of an ailment and the name of an organ the seat of that ailment should be abandoned; and the exemption of medicines generating carbonic-acid gas should be omitted. Further, any reference in advertising matter to the government stamp should be prohibited, and a name of a proprietor or firm should be printed on the stamp.

"2. That the Indecent Advertisements Act be amended on the lines of Lord Bray's Bill."

In addition to the foregoing amendments, the committee recommends the following legislative enactments:

"1. That every medicated wine and every proprietary remedy containing more alcohol than that required for pharmacological purposes be required to state on the label the proportion of alcohol contained in it.

"2. That the advertisement and sale (except the sale by a doctor's order) of medicines purporting to cure the following diseases be prohibited:

Cancer	Diabetes	Locomotor ataxia
Consumption	Paralysis	Bright's disease
Lupus	Fits	Rupture (without operation or appliance)
Deafness	Epilepsy	

"3. That all advertisements of remedies for diseases arising from sexual intercourse or referring to sexual weakness be prohibited.

"4. That all advertisements likely to suggest that a medicine is an abortifacient be prohibited.

"5. That it be a breach of the law to change the composition of a remedy without informing the department of the proposed change.

"6. That fancy names for recognized drugs be subject to regulation.

"7. That the period of validity of a name used as a trade mark for a drug be limited, as in the case of patents and copyrights.

"8. That it be a breach of the law to give a false trade description of any remedy, and that the following be a definition of a false trade description:

"A statement, design, or device regarding any article or preparation, or the drugs or ingredients or substances contained therein, or the curative or therapeutic effect thereof, which is false or misleading in any particular."

"And that the onus of proof that he had reasonable ground for belief in the truth of any statement by him regarding a remedy be placed on the manufacturer or proprietor of such remedy.

"9. That it be a breach of the law:

"(a) To enclose with one remedy printed matter recommending another remedy.

"(b) To invite sufferers from any ailment to correspond with the vendor of a remedy.

"(c) To make use of the name of a fictitious person in connection with a remedy. (But it should be within the

power of the department to permit the exemption of an old-established remedy from this provision.)

"(d) To make use of fictitious testimonials.

"(e) To publish a recommendation of a secret remedy by a medical practitioner unless his or her full name, qualifications and address be given.

"(f) To promise to return money paid if a cure is not effected.

"In conclusion, the committee believes that departmental and legislative action as outlined above will not inflict injustice on any patent or proprietary medicine or appliances; that it will, alike by its operative and its deterrent effect, afford the public efficient and urgently needed protection against injury and fraud; and that no measures of a smaller scope will secure this result."

Correspondence

The Levator Ani versus the Bulbocavernosus in Pelvic Floor Repair

To the Editor:—On page 540 of THE JOURNAL of Aug. 15, 1914, appears the following statement by Goldspohn: "The bulbocavernosus, surrounding the vulvar opening, reenforces the inner margin of the trigon; and these together are what some operators have mistaken for the levator ani, whose anterior median edges lie farther within, are less distinct and extend more in an inward and upward direction. This mistake is apparent from the illustrations and described technique [italics mine] of Robert T. Morris, Arnold Sturmdorff, C. A. Hall, George B. Somers and C. W. Barrett." It is true that these names were not read in the presentation of his paper, no doubt to spare our feelings.

In the printed discussion he says: "While Dr. Barrett may now be going deep enough to seize the levator, he has repeatedly mistaken the inner edges of the trigon and the bulbocavernosus muscle as the levator ani in his illustrations." Dr. Goldspohn's comment, in closing the discussion after my lantern-slides were shown at Atlantic City, was, "Dr. Barrett's illustrations now show that he goes deep enough but," etc. [italics mine].

As I have laid stress for years on the importance, not only of going deep enough to get the levators, but of actually picking up the levators as we would pick up the definite anatomic structures in doing an inguinal herniotomy, I must insist that Dr. Goldspohn is mistaken, and present the following description of my work as it appears in the article quoted by him as proof thereof:

The first part of the article takes up the anatomy, embryology, comparative anatomy and variations of the levator ani muscle and its importance as a part of the closure of the abdomen in upright animals, and the importance of dealing with this muscle in pelvic floor repair. It lays stress on the importance of starting the flap at the vaginovesibular junction so as not to close the vagina with vulvar structures. It then reads: "The dissection is carried between the vagina and rectum until we are above the levator ani muscle (about 1½ inches) and well to the sides to uncover these muscles. The guide is not to be indicated in inches, however, as the test is to be able to find the muscle. With the flap held forward the index finger of the left hand crowds the rectum backward and puts the levator on the stretch. With a strong round curved needle that would about fit the three-eighths circumference of a silver half dollar, and threaded with catgut, we pick up a good bite of the left levator ani muscle as far forward as we wish to unite it; we then include a little of the deep part of the flap, after which the needle picks up a corresponding portion of the levator muscle on the right side. With the same suture and needle we now go back to the left side and pick up the levator ani muscle one-half inch nearer the rectum; the needle is then made to pick up a portion of the rectal wall, after which it picks up a corresponding portion of the levator muscle on the right side" (Barrett: Obstetrics and Diseases

of Women, April, 1909). The description continues in detail to the complete closure of the wound. Conclusion 10 reads: "Two points should be observed in the herniotomy of the pelvic floor: (a) The levator ani muscles should be reunited. (b) Superficial vulvar structures should not be reunited but left with the natural vulvar opening into the vagina, which may easily be accomplished by making the V-shaped incision at the lower end of the vagina instead of the usual incision in the labia majora."

This form of perineal hernioplasty has been demonstrated to many who have honored me by their presence, and is not so complicated as Dr. Goldspohn seems to think.

CHANNING W. BARRETT, M.D., Chicago.

The above correspondence was referred to Dr. Goldspohn, who replied:

To the Editor:—I read my paper at the Atlantic City meeting in more abbreviated form than was needed to remain within the time limit. I said in closing the discussion, in substance, that I believe that Dr. Barrett is now (meaning recent years) going deep enough within the pelvis to deal with the levator, or that he probably does so; but that he has an illustration in his first publication on this subject (*Am. Jour. Obst.*, etc., April, 1909, p. 565), in which he represents the levator ani muscle as lying in an altogether more conspicuous and superficial position than it is possible to show it in any normal dissection, unless the urogenital trigon and the bulbocavernosus muscles have first been dissected off. This is an anatomic fact, which Dr. Barrett cannot deny without taking issue with the authorities on anatomy cited in my paper; and criticism is in order as long as he does not admit the mistake set forth in that illustration.

ALBERT GOLDSPOHN, M.D., New York.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted on request.

TEST FOR PURITY OF WATER

To the Editor:—1. Please inform me as to a simple test for purity of water.

2. What is best to use to rid a well of unpleasant odors arising, I think, from the overflow into it of surface water impregnated with alkali earth.

JAMES D. KENNEDY, M.D., Ganado, Ariz.

ANSWER.—1. If by "purity" of water is meant inability to convey disease, there is no simple test. Determination of the relative abundance of *Bacillus coli* in a water is perhaps the most important single method now in use, but it must be employed with great care and the results can be properly interpreted only after long experience in water analysis.

2. Unless the source or nature of the unpleasant odor is known it is impossible to tell how to prevent it. Surface water should not be allowed to enter any well. Consult your State Board of Health in regard to the whole question. The board will perhaps make analyses or inspection for you.

CAUSE OF EYELID QUIVERING—COMPOSITION OF "MUM"

To the Editor:—1. I have a patient, woman, aged 52, who for three months has had a marked "quivering" of the right eyelid. Several physicians have tried "practically everything" without giving any relief. At times these contractions of the lower lid and cheek muscles are so violent that the patient is unable to work or sleep. Physical examinations have proved negative. A slight refractive error was corrected two months ago.

2. Can you give me the composition of "Mum," a deodorant of perspiration made by the Mum Manufacturing Company of Philadelphia? I have recently seen a case of a peculiar axillary dermatitis in which this preparation may have caused the trouble. What is the usual deodorizing substance in these toilet articles?

E. E. WISEHART, M.D., Snow Hill, Md.

ANSWER.—1. It is rather difficult to offer any very intelligent advice without knowing more about the daily life and habits

of the patient. Has an examination of the accessory nasal cavities been made? Have the teeth been examined, especially those on the right side of the upper jaw? Have the physical examinations failed to show the presence of any general toxemic condition? Does the woman use her eyes excessively for close work of any kind: reading, writing, sewing, etc.? If the foregoing examinations prove negative, it would be wise to have her eyes thoroughly examined under complete cycloplegia so that the refractive error as well as the amount of presbyopia present can be absolutely corrected and the muscle balance carefully worked out. A greatly diminished power of prism convergence especially in eyes under excessive strain, could easily produce reflex symptoms of this kind.

2. This query was answered in *THE JOURNAL*, Nov. 30, 1912, p. 1993.

LITERATURE ON STATE CONTROL OF TUBERCULOSIS

To the Editor:—I have been appointed one of a commission of five to draw up a comprehensive plan for a thorough antituberculosis campaign in this territory, which plan we are to submit to the Governor not later than Jan. 1, 1915. I wish you would give me a list of books on the subject from which I might get the best idea about hospital formation, sanatoriums, etc., and the various methods of handling this subject by the State Board of Health. With our delightfully even climate we should be able to eradicate this disease almost entirely.

A. I., M.D., Hawaii.

ANSWER.—The following is a list of books and pamphlets; further references are contained in most of these:

Some Plans and Suggestions for Housing Consumptives, National Association for Study and Prevention of Tuberculosis, 105 East Twenty-Second Street, New York.

Battling for Health at Mont Alto, *Pennsylvania Health Bull.*, October, 1912.

A LETTER BY JENNER

To the Editor:—Pasted to the back of the title-page of a book entitled "Professional Anecdotes, or Ana of Medical Literature" (London, 1825, in three volumes, I having Volume II), is an original letter written by E. Jenner. I enclose a copy.

MAX ISENBERG, M.D., New York.

The letter reads:

Cheltenham, Jan. 16, 1807.

Dear Sir.—I congratulate you and Mrs. Phillips on the addition to your flock. It is my intention to be in town soon; but how soon I cannot at the present moment positively say. My movements will be regulated by those of the College of Physicians and the House of Commons. The former have not yet finished their inquiry, which will, when completed, be laid before the House.

This inquiry will lay all those troublesome ghosts which have so long haunted the metropolis with their *ox-faces*, and dismal hootings against vaccination. However, tis all for the best—you may depend upon it the new investigation will prove the touchstone of the vaccine discovery.

I have not yet seen your monthly magazine for the present month. Probably you may not have inserted the very curious and interesting piece of intelligence I recd. from Madrid. This supposition induces me to enclose it. What a glorious enterprize! I have made peace with Spain, and quite adore her philanthropic monarch. Could not this be touched upon by some of those who, *thru' you*, introduce [I cannot decipher the next word] into the world? A word more respecting your little one. Altho' I should be happy to shield it myself from the speckled monster, yet I would advise you not long to wish my coming to town. I will just add that I consider the vaccine lancet in the hand of John Ring, just as safe as in my own.

Pray present my best wishes to Mrs. Phillips and tell her I have not forgotten her civilities.

Yr. very faithful St.

E. JENNER.

LIGHT AUTO FOR PHYSICIAN

To the Editor:—I am seeking information regarding the experience of those who have driven the lighter makes of automobiles. The car I use weighs about 2,000 pounds, and while it gives excellent service as far as speed and power are concerned I find the up-keep expensive as to tires. The country in my section is somewhat rocky and hilly, the territory is rather large and we find a fast car a necessity. Any information I may receive will be much appreciated. Does any one know anything about or use the lately advertised tandem seated cars?

M. J. S., Kansas.

WEST VIRGINIA: Clarksburg, October 13. Sec., Dr. S. L. Jepson, 81 Twelfth St., Wheeling.

Requires Hospital Intern Year

The annual announcement of the University of Vermont, College of Medicine, just received, states that all students matriculating after Jan. 1, 1915, in addition to the usual four-year course will be required to take a fifth year as an intern in some approved hospital before they are eligible for the degree of Doctor of Medicine. This is the fourth college which has adopted this requirement. The complete list and the session when the requirement became or will become effective are as follows:

	Session of
University of Minnesota Medical School.....	1910-11
Leland Stanford Jr. University School of Medicine.....	1914-15
Rush Medical College (University of Chicago).....	1914-15
University of Vermont College of Medicine.....	1915-16

One state licensing board, that of Pennsylvania, now requires that every candidate to be eligible for a license to practice medicine in that state, must have served at least one year as an intern in an approved hospital. The requirement became effective in 1914.

University Graduate Schools of Medicine.

The annual announcement of the University of Minnesota Medical School, just received, includes information regarding a Graduate School of Medicine. The complete list of university graduate medical schools and their location is as follows:

	Location
University of Alabama, Graduate School of Medicine.....	Birmingham
University of California, Graduate School of Medicine.....	Los Angeles
Tulane University Post-Graduate School of Medicine.....	New Orleans
Harvard University Graduate School of Medicine.....	Boston
University of Minnesota, Graduate School of Medicine.....	Minneapolis

The opening of such schools in this country by high grade universities is very encouraging and gives assurance that graduate medical instruction on a high plane is rapidly becoming more available in this country.

New York Reciprocity Report

Mr. H. H. Horner, chief of the Examination Division of the New York Education Department, reports that 7 candidates were licensed through reciprocity and one candidate on exemption, from January to June, 1914. The following colleges were represented:

LICENSED THROUGH RECIPROCITY

College	Year Grad.	Reciprocity with
Dunham Medical College, Chicago.....	(1902)	Indiana
Univ. of Mich., Dept. of Med. and Surg., (1910; 2)	(1912)	Michigan
Eclectic Med. Coll. of the City of New York.....	(1912)	New Jersey
Miami Medical College.....	(1908)	Ohio
Medico-Chirurgical College of Pennsylvania.....	(1899)	New Jersey

LICENSED ON SPECIAL EXEMPTION CLAUSES

	Year Grad.	Indorsed Total No.
Jefferson Medical College	(1886)	1

Book Notices

DIE PROGNOSESTELLUNG BEI DER LUNGENTUBERCULOSE mit eingehender Berücksichtigung der physikalischen und serologischen Befunde und der therapeutischen Prognostik. Bearbeitet von Priv. Doz. Dr. D. O. Kuthy und Dr. A. Wolff-Eisner. Paper. Price, \$4.50. Pp. 572, with 21 illustrations. New York: Rebman Company, 1914.

The authors discuss one of the most important questions of medicine, namely, the prognosis of pulmonary tuberculosis. The importance attached to prognosis is indicated by the fact that it is about the first question to be asked by the patient, who values diagnosis chiefly because it enables the physician to predict correctly the outcome of the disease. The former opinion made the question of prognosis depend almost entirely on the correctness of the diagnosis, since a positive diagnosis of pulmonary tuberculosis was held to mean an absolutely unfavorable prognosis. The advance of science showing the frequency of recovery from pulmonary tuberculosis has made this simple prognosis untenable. The diagnosis must be more carefully made to discover conditions which may have favorable or unfavorable influences on the final outcome. The heredity must be thoroughly worked out and the past history of the patient diligently explored for indications. The authors discuss first these historical data. The prognostic significance of sex, age, occupation, financial situation, temperament, etc., are considered. In a similar way, the present condition of the patient is inquired into and the prognostic significance of the individual symptoms and objective findings thoroughly discussed. The authors then take up the effect of various treatments on prognosis, such as the tuberculin treatment in all its forms. Spengler's I. K. is regarded as still on trial but must not, as has been done, be set down as inactive. It is evidently capable, in some cases, of doing harm. It is possible in the space at command only to indicate the scope of the work. To consider critically the various aspects of the subject and the multitude of various questions raised is impossible. The volume is completed by a list of more than a thousand references to the literature. Considering that most of these references are accompanied in the text by brief abstracts of the respective articles, an idea may be gained of the research whose results are embodied in this volume.

A MANUAL OF INFANTILE PARALYSIS WITH MODERN METHODS OF TREATMENT, INCLUDING REPORTS BASED ON THE TREATMENT OF THREE THOUSAND CASES. By Henry W. Frauenthal, A.C., M.D., Surgeon, New York Hospital for Deformities and Joint Diseases, and Jacolyn Van Vliet Manning, M.D. Cloth. Price, \$3. net. Pp. 374, with illustrations. Philadelphia: F. A. Davis Company, 1914.

The authors have here collected a large amount of information concerning infantile paralysis (anterior poliomyelitis)—historical, epidemiologic, etiologic, diagnostic and with reference to its management and treatment—together with a discussion of various theories that have been formulated about it. Interesting are epidemiologic studies of Manning of the Wisconsin epidemics, the statistics with reference to coincident animal paralyses, tables of epidemics and pandemics and the results of animal experimentation. The chapter on differential diagnosis, containing descriptions of the different types of cases, is a valuable one. The considerable portion of the book is devoted to treatment in the acute and preparalytic stages and of the paralyses and deformities resulting from the disease. This is of practical worth to the practitioner as well as to the orthopedist; it

offers definite advice, justified by a large experience in an institution for the treatment of such cases. The high-frequency current is recommended as soon as paralysis has occurred, and other physical measures are emphasized and persistence in their employment insisted on. Especially is it important to employ and persist in measures or exercises which require voluntary effort on the part of the patient, no matter how feeble the response may at first be. Scoliosis, one of the deformities discussed, is attributed to poliomyelitis as the etiologic factor in most instances. Mechanical and surgical measures are set forth, the latter including tendon, nerve and muscle transplantation, though the authors have not much that is new to offer along these lines, and, indeed, insist that the other methods of treatment should first be given the most extended and patient trial. The book is quite satisfactory on account of its definiteness of statement regarding the management of a disease whose sequelae are most deplorable and whose treatment has hitherto not been productive of much success in the way of results.

DAS ULCUS DUODENI. Von Dr. J. Schrijver, Arzt für Magen- und Darmkrankheiten in Amsterdam. Paper. Price, 10 marks. Pp. 184, with 16 illustrations. Berlin: S. Karger, 1914.

The new interest in ulcers of the digestive tract which has followed the investigations of Moynihan and of the Mayo brothers found gastrologists in general, and particularly those of the Continent, rather unprepared for the revelations of the surgical clinic. The profession of England and America readily accepted the new views, especially as to the frequency of ulcer of the duodenum to which Moynihan assigned so characteristic a clinical history, but the clinicians of Germany have been somewhat slow to acquiesce. Schrijver adds his testimony to that of others as finding in a large proportion of cases an ulcer of the duodenum as the cause of chronic dyspepsia from which the patients were happily relieved by timely surgery. His book gives a systematic account of the disease and closes with the histories of a series of thirty-seven cases selected from ninety-five cases occurring in his experience in the last three years. The book is illustrated with a number of plates and several roentgenograms, the latter, however, having an indefiniteness which impairs their utility to most readers.

ABNORMAL PSYCHOLOGY. By Isador H. Coriat, M.D., Second Assistant Physician for Diseases of the Nervous System, Boston City Hospital. Second Edition. Cloth. Price, \$2 net. Pp. 428. New York: Moffat, Yard & Co., 1914.

The whole field of abnormal psychology is undergoing modification, influenced by the introduction of Freud's theories and the psychoanalytic method of study. This new edition of Coriat has been enlarged by some general outlines of Freudian principles. "For reasons of space" and "because such material does not really lend itself to popular presentation" the author does not go into the subject fully. He is evidently troubled by qualms of which some exponents of the newer psychology have not complained. The theory of dreams is explained in simple language, and there is a new chapter on the prevention of the neuroses and a reprinted article on colored hearing. The book has advanced parallel to recent studies in abnormal psychology and is a worthy publication for those especially interested in the subject.

THE PRACTICE OF SURGERY. By James Gregory Mumford, M.D., Lecturer on Surgery in Harvard University. Second Edition. Cloth. Price, \$7. Pp. 1032, with 683 illustrations. Philadelphia: W. B. Saunders Company, 1914.

Three years have elapsed since the publication of the first edition of this book. The author has revised the text to keep it abreast of progress, although in the past few years no revolutionary change in surgery has occurred. New cases are cited to illuminate the text and new pictures are added. The book is therefore strictly up to date, and as a clinical surgery cannot fail to prove of value to the reader. The author's style is pleasing, clear, direct and concise in exposition. The many beautiful illustrations are a valuable addition to the text.

Miscellany

A Combined Office and Residence

To the Editor:—My wife and I have been interested in the views and ground-floor plans of physician's offices and residences printed in *THE JOURNAL* from time to time. While many of them are convenient and attractive, we have failed to see one yet that we like so well as ours. I am enclosing a drawing of the first floor plan.

This building was designed by ourselves about twelve years ago, and, since the residence part pleases Mrs. Dunn and the office suits me, there must be many good features about the house as both of us are rather particular. The office has a conspicuous place in the house without relegating the living rooms to the rear, commands a view of two streets and their corner, and is easy of access from the front. The parlor and library both front a street also. The hall separates the two departments of the house from each other entirely. The kitchen is entered by a walk and porch from one street and the dining room by the same arrangements from the other street. The house is built on a lot 67 by 50 feet and the outside dimensions are 50 by 32 feet. The upper story is not shown, as physicians would hardly be interested in this, but I will say that every room upstairs fronts one of

First-floor plan of combined office and residence.

the streets, excepting the bathroom, and all are of good size. While we admit that the house is not built along conventional lines, we believe it has many features that will commend it to the physician planning to build a combined home and office.

JAMES W. DUNN, M.D., Cairo, Ill.

Is Loco-Weed Disease a Myth?

Poisonous properties have long been ascribed to the pretty, luxuriantly blooming leguminous plants known to the Western cattle ranges as loco or crazy weeds. Being hardy and able to maintain themselves in poor soil, these plants, of two or three main types, are found widely distributed from British America to Mexico and from Kansas to California. Stock-raisers have attributed great losses to the disease caused in horses, cattle and sheep by the eating of this weed, and the state of Colorado paid out nearly \$200,000 in bounties for attempts at its extermination between 1881 and 1885.

The theory of Crawford (Crawford, A. C.: Barium, a Cause of the Loco-Weed Disease, Bull. 129, Bureau Plant Ind., U. S. Dept. Agric., 1908. Editorials, *THE JOURNAL*, Feb. 8, 1908, p. 458, Oct. 17, 1908, p. 1338) that barium causes loco poisoning was rejected by Marsh and Alsberg and Black (Marsh, C. D., Alsberg, C. L. and Black, O. F.: The Relation of Barium to the Loco-Weed Disease, Bull. 246, Bureau Plant Ind., U. S. Dept. Agric., 1912. Editorial, *THE JOURNAL*, Dec. 21, 1912, p. 2258) on the grounds (1) that barium poison-

ing does not produce the symptoms typical of "locoed" animals; (2) that antidotes to barium have no effect on loco poisoning; (3) that admittedly harmless plants occupying the same areas as the loco-weed contain barium in comparable quantities, and (4) that the barium found in dried loco-weeds is present in almost insoluble form. These investigators, however, do not question the existence of loco-weed disease; in fact, they claim to have produced it experimentally in horses and cattle. They merely leave the question of its cause an open one.

H. T. Marshall, in a recent article (*A Summary of Studies of Loco-Weed Disease of Sheep, Johns Hopkins Hosp. Bull.*, August, 1914, p. 234), based on studies of the sheep of Montana, begun eleven years ago for the Department of Agriculture, though not published by the department, takes the point of view that the condition designated as loco disease is not a single clear-cut malady. In his experience the descriptions given by various ranchmen of the symptoms and cause of the disease did not tally with each other; and necropsy studies on supposedly locoed sheep from different flocks disclosed different conditions. Some sheep were heavily infected with a liver tapeworm (*Thysanosoma actinioides*), others with the sheep-fly (*Oestrus ovis*). Marshall found the ranges too frequently grazed over and the flocks too large for the available grazing-grounds. In his opinion, all the symptoms attributed to loco poisoning could be accounted for by undernourishment and infections. In an attempt to produce loco disease experimentally, four lots of sheep were segregated. One group was fed abundantly on alfalfa, another on half rations of alfalfa, a third on loco-weed without alfalfa, and a fourth on loco and alfalfa. It was found that the sheep fed on loco-weed without alfalfa suffered from starvation; but those fed on alfalfa and loco kept in better condition and gained more in weight than any of the others. None of the animals receiving loco showed any characteristic symptoms. Sheep-fly disease attacked all the flocks during the course of the experiments. The starved animals suffered most, those fed on loco and alfalfa least. Marshall's conclusions are that there are several diseases masquerading under the name of "loco disease," that the existence of any disease definitely attributable to the loco-weed remains to be proved, and that the interests of Western stock-raisers can be best served, not by a campaign against the presumably innocent loco-weed, but by combating the parasitic diseases prevalent on the ranges, as well as the overstocking of ranches and the underfeeding of stock.

It may occur to the reader that Marshall's experiments and observations appear to indicate that sheep are not susceptible of loco poisoning, but not necessarily to prove that this disease has no existence. Marshall says that he could find no locoed animals other than sheep for study even after extended search on the Montana ranges. It seems regrettable that his experimental work did not include cattle and horses.

Efficacy of Tartar Emetic in Superficial Leishmaniasis

G. Vianna of the Instituto Oswaldo Cruz at Rio de Janeiro relates that in Brazil nothing seems to act so effectively on leishmania lesions of the skin and mucous membranes as antimony and potassium tartrate by intravenous injection. The experiences there with salvarsan and neosalvarsan have been entirely negative as far as curing lesions of this nature in the integument. The efficacy of tartar emetic in trypanosomiasis having been thoroughly established in his experimental and clinical experience, he applied it also in a number of cases of destructive leishmania lesions of the face and nasal mucosa, and gives a series of illustrations "before and after," in his article on the subject in the *Annales Paulistas de Med. e Cir.*, 1914, ii, 167. The maximum dose was 10 c.c. of a 1 per cent. solution of the tartrate in physiologic saline sterilized by filtration. He commenced with small doses and in the chronic cases kept up the smallest doses for a long time. He gave the intravenous injections by this technic even to children of 5 and to patients over 60, and never noticed any untoward by-effects except in two cases of nephritis in which

the albumin increased in the urine and edema developed under the large doses; on reducing the dose no further injury was apparent even in these cases. The symptoms showing that the limit of tolerance has been passed are pains in joints and muscles or headache. In the patient shown before and after treatment, the destructive affection in the nose and larynx was of five years' standing and was accompanied by extensive ulcerative processes on the legs, all completely cured under the antimony and potassium tartrate treatment.

Fundamentals in Teaching Sex Hygiene

Most of the plans for introducing the subject into the home and school insist that the facts of human reproduction should be taught to the child by an indirect method. This indirect method J. C. Hollister (*Cal. State Jour. Med.*, July, 1914) believes to be wrong, because it does not rest on what to his mind are the fundamentals of sex education. The fundamentals are not to be found in general biology or nature study; they are not plant or animal reproduction; they are not cells nor evolution nor life itself. They are human anatomy and physiology. Any plan that does not recognize the truth of this, any plan that does not rest on these foundations, is inherently weak. It is unnatural, illogical, and has not a sound psychologic basis. If this be true, the child should have a knowledge of human anatomy and physiology before it can appreciate the matter in sex education.

Hollister claims that: 1. Human anatomy and physiology can be taught successfully to the young child. 2. The knowledge of normal human anatomy and physiology is particularly advantageous to the child. 3. There are no important reasons why the genital system should not be taught as part of general anatomy and physiology. 4. Such a plan rests on a sound psychologic basis.

An Economic Aspect of Vaccination

In a recent bulletin of the Rochester (N. Y.) Chamber of Commerce appears the following note from G. W. Goler, the health officer:

"You have noticed that it is our intention to temporarily use the small-pox pavilion at our Municipal Hospital for the treatment of drug habitues. One of the reasons for our being able to do this is because our city has been so remarkably free from small-pox that the small-pox pavilion is vacant most of the time. Rochester is unique in that respect, from the fact that a large number of the large employers have refused to employ men unless they have been successfully vaccinated. Now if we could get more firms to insist on vaccination as a prerequisite for employment we might be able to go for a much longer period without cases of small-pox, and thus be able to use our small-pox pavilion for other purposes."

In these days of stringent economy it will be found that the most important economy is the conservation of the public health.

Mistakes and Sins

"We make mistakes; other people commit sins." A wrong diagnosis after due examination (a thing that happens to all of us) is a mistake, and a pardonable one; a wrong diagnosis arrived at without due examination (a thing that happens to the other fellows) is a sin; medically speaking, it is "the unpardonable sin." That an examination was not allowed is no excuse for a wrong diagnosis. If you cannot convince the patient that an examination is necessary, quit the case; for it is better to lose a patient than to lose reputation. Moreover, do not treat first and examine afterward; for then you may be called on to treat, not only the disease, but also the effects of your own treatment. After an examination has been made, if still in doubt, admit it. If you do not know enough about the case to satisfy yourself, it is not safe to assume that you know enough about it to satisfy the patient; this is not only indifferent ethics, but also bad policy. —Arthur E. Giles. *Clinical Journal*.

Medicolegal

Validity of Statute Providing for Licensing of Practitioners of Specialties

(*Bohannon vs. State Board of Medical Examiners et al* (Cal.), 140 Pac. R. 1089)

The District Court of Appeal of California, First District, reverses a judgment which sustained the defendants' general demurrer to the complaint in this action wherein the plaintiff claimed that it was the duty of the defendants, as the Board of Medical Examiners, to issue to him a certificate authorizing him to practice a special branch of medicine and surgery. He based his claim on the amendment of 1911 to the medical practice act which provided in substance that the medical examiners might issue a certificate to any person who had practiced a special branch of medicine and surgery for a period of not less than thirty-five years, fifteen years of which time had been within the state of California. The trial court was of the opinion that the amendment, so far as it provided for special certificates, was unconstitutional, for the reason that the classification was unreasonable. The court of appeal however holds otherwise, and a rehearing has been denied by the Supreme Court of California.

The court of appeal says that the provisions of the act complained of clearly show a legislative intent to admit certain persons to practice a special branch of medicine and surgery who have previously violated the law, not because they have violated the law, but because of an acquired experience in given branches of medicine or surgery. It is conceded that the act of the legislature may not have been the most expedient or salutary, but the courts are not concerned with the good or bad policy exercised by that branch of the government. The only argument against the classification here adopted is that it extends a certain exemption to a particular class who for a certain period have been practicing illegally. Does this illegal practice of itself deprive the legislature of the right to adopt regulations under which the persons in this class as such may gain the right to practice medicine and surgery? This court is of the opinion that the question must be answered in the negative. Moreover, the applicant is not qualified for practice by the number of years of his violation of the law, but he must pass an examination, and in addition thereto give a practical demonstration of his successful practice in a special branch, and even then, if he successfully pass these tests, a right to practice the special branch in which he is experienced and proficient only is conferred on him.

The applicant in this case specified as the "special branch of medicine and surgery" which he desired to practice, "the treatment of cancers, tumors, malignant growths and cutaneous diseases." This court cannot judicially say that these disorders are not so correlated that they cannot be classed as a "special branch of medicine and surgery." This question is a matter for determination by the trial court under competent evidence.

Loss of Eye Due to Infectious Disease

(*McCoy vs. Michigan Screw Co.* (Mich.), 147 N. W. R. 572)

The Supreme Court of Michigan says that several small pieces of steel from the lathe machine on which the claimant was working lodged in his eye. This, it was claimed, caused an irritation and caused him to rub his eye. At the time he was being treated for gonorrhea. Six days after the accident he went to another physician, who removed four pieces of steel from the eye. The next day the physician removed another piece of steel and discovered that the eye had become infected with gonorrhea. The man was then sent to a hospital and subsequently lost the sight of the eye. The industrial accident board affirmed an award made by an arbitration committee of \$6.49 a week for 100 weeks, under the workmen's compensation act. But the decision of the board is reversed by the court, which holds that the facts were not

capable of supporting the inference that the injury arose out of and in the course of the employment. The court says that the claimant contended that the germs would not have entered the eye had not the steel caused "(a) an inclination to rub—the inciting cause—(b) inflamed condition which made the eye susceptible to the entry of the germs, as in the case of blood-poisoning and erysipelas." It was not reasonable to say, however, that he would not have rubbed his eye if the steel had not lodged there. He might not have rubbed his eye, it was true; but it was just as reasonable to suppose that he might have had occasion to rub his eye without this particular inciting cause. By the medical testimony it conclusively appeared that the infection could have taken place if the steel had not been there. It must be said, from this record, that the loss of the eye was directly and immediately due to the infection caused by the gonorrhea, which it could not be claimed was a risk incident to the employment.

Practice of Medicine by Christian Scientist

(*People vs. Cole* (N. Y.), 148 N. Y. Sup. 708)

The Supreme Court of New York, Appellate Division, First Department, affirms a conviction of the defendant of practicing medicine without lawful authorization and registration. The court says that the defendant testified that he had been for eight years an authorized practitioner of the Christian Science Church, and that he had maintained an office in a certain building for five years; that when he received his first knowledge of Christian Science he was a sculptor and a poet; that he had never studied medicine in any way; that his average income from his practice was about \$5,000 or \$6,000; that he did not ask people for money for treating them, but when they tendered it he took it.

The statutory definition of the practice of medicine is broad enough to cover the acts of the defendant because he "holds himself out as being able to . . . treat . . . any human disease," and he did "undertake to treat." The language of the statute is "by any means or method." This covers the means or method used by him. While he denied the material existence of disease and said it was merely mental, yet he undertook to treat people he called patients for what they told him was the matter with them; in other words, what they thought were diseases. He had an office for that purpose; he received fees therefor; he habitually termed what he did his "treatment." He conducted a peculiarly successful business. He called himself a practitioner, but admitted that the popular phrase was healer. Whatever the believers may think about disease, the law regards it as a fact.

The one question presented here was whether the defendant was permitted to do what he did under the clause of the statute which provides that "This article shall not be construed to affect . . . the practice of the religious tenets of any church." Is the commercialized use of prayer for the avowed purpose of treating all persons seeking cure for all kinds of bodily ills the practice of the religious tenets of a church? In this case this court has no right, and does not presume, to pass on the faith, belief or religious tenets of the Christian Scientists or the efficacy of the methods of their practitioners in treating disease or error. Its sole concern is whether on the facts proved the defendant was properly convicted of practicing medicine without being licensed and registered, and whether the conceded acts come within the exception as to the practice of the religious tenets of any church. "Tenet" is defined by the Century Dictionary as "any opinion, principle, dogma or doctrine which a person, school or sect holds or maintains is true." A man's right to hold and express such is unquestioned. But when he advances from the realm of thought to that of action, he must obey the law. The court reaches the conclusion that the acts complained of constitute the practice of medicine, were not the practice of the religious tenets of any church, and to authorize the defendant to administer the treatment, which he conceded he did, he must have first been duly licensed and registered in accordance with the provisions of the public health law.

- 3 Analysis of Deaths Occurring in Course of 1,573 Surgical Operations. E. MacD. Stanton, Schenectady.
2. Spasmodic Closing of Cerebral Arteries.—Gordon has followed up fourteen cases of this character. Six of the patients are still living; eight died and Gordon succeeded in obtaining permission for autopsies. Every one of the patients was seen by him in each attack. A close analysis of both groups of cases demonstrate one common fact that besides embolism, thrombosis and hemorrhage which are considered as the classical causes of apoplectic strokes there is also a condition which is of hemiplegic or hemiparetic character, but which is produced not by a material lesion of the blood-vessel, but by such a functional disturbance of the vessel wall as to interfere with the circulation and therefore with the function of the nerve tissue supplied by this blood-vessel. The temporary character of this disorder of function, the prompt or rapid recovery from the interfered function, finally and especially the intermittence and frequent repetition of the attacks—all these facts speak in favor of a condition which is totally different from a material obstruction of a vessel with an embolus or thrombus or from a hemorrhage. Intermittent closing and opening of the cerebral vessels are in Gordon's opinion, the only possible explanation of the temporary paralysis. Hemorrhage, embolism and thrombosis could not possibly be taken into consideration in the production of brief and intermittent attacks. Diminution or possible avoidance of arterial irritability is the prime factor in the management of cases of this character.

4. Renal Lesions of Cholera and Acidosis.—Investigation of the ordinary forms of chronic and acute renal disease

have shown that the increase in tolerance to bicarbonate which was found to occur in the uremia of asiatic cholera is not specific for the nephritis of cholera. It occurs not only in nephritis arising from other infections, but also in nephritides which are free from infection. The cause of this increase in tolerance in cholera Sellards believes is almost certainly due to an acidosis; that is, to an impoverishment of the sources of fixed bases in the body. It is conceivable that this deficiency in carbonates is perhaps due to two factors, namely, (1) a diminished excretion of acid on account of the urinary changes; (2) and a loss of alkali directly by the bowel. The conditions in asiatic cholera afford evidence of the inadvisability of distinguishing between relative and absolute acidosis.

The cause of the increased excretion of ammonia in cholera is not known. Two factors must be considered in its explanation namely, (a) the possibility of a primary disturbance of protein metabolism with defective synthesis of urea, and (b) a secondary disturbance of metabolism with an accumulation of ammonia to compensate for an acidosis. The evidences of acidosis in the uremia of cholera are sufficiently definite to constitute a rational basis for treatment of this condition with alkalis. The examination of the urine or the blood affords a rational guide of the amount of bicarbonate to be administered. The available evidence indicates that it is advisable to give a mildly alkaline solution ($\frac{1}{2}$ of 1 per cent. of sodium bicarbonate) early in the course of the disease, before an out-spoken uremia has developed, increasing the quantity if symptoms of uremia appear. As much as 100 gr. of bicarbonate may be required in the course of two or three days. The quantities, which have been recommended in the text-books, Sellards says, are wholly inadequate to restore the body to its normal content in carbonates. Moreover, the dosage is determined without any guide other than the general condition of the patient. The modifications of alkaline therapy for cholera, suggested by Wherry, is unnecessarily intensive. A limited use of the normal carbonate in cholera has led Sellards to believe that it is distinctly dangerous, especially in the early stage of the disease, when the administration of alkaline therapy promises most.

9. Treatment of Whooping Cough.—The medicinal treatment of pertussis is divided by Graham into two parts: First, drugs or other methods that *per se* have a tendency to lessen the number and severity of the paroxysms. Second, drugs or other methods that are directed to the treatment of the complications of pertussis. To the first an unusual amount of attention has been given; to the second, comparatively little. Among the drugs that *per se* are useful in pertussis is mentioned belladonna. Graham prefers using the tincture, beginning with 1 drop, three times a day, and increasing the daily quantity by 1 or 2 drops until mild physiologic effects of the drug appear, when the increasing of the dose must be cautiously continued.

Antipyrin Graham has never used in the frequent doses so often advised. A single dose at bed-time, or a morning and evening dose has been, in his experience, as much as it was wise to employ. To a child 2 years he gives 2 or 3 grains each night, or morning and night. Bromid of soda, grains v, 3 or 4 times a day, to a child of 3 years, is often of benefit, and codein, trional, heroin, and chloral are often of benefit in allaying cough and inducing sleep. They may be given in a single dose at bed-time, or, if necessary, 2 or 3 times a day.

Quinin has been used in large doses and when so given may reduce not only the number, but also the severity, of the paroxysms. It is not an antispasmodic, and if it produces any effect in these large doses, Graham says, it must be due to some effect on the causal bacillus. Quinin lactate, 10 gm. saline solution, 100 gr. of which $2\frac{1}{2}$ c.c., warm, is injected intravenously, may be used. If given hypodermically into the muscles the effect is favorable, but not as prompt nor as satisfactory as when given intravenously. Hydroquinin has been employed both intravenously and intramuscularly, but its action is more favorable when injected into the vein. A daily dose is given for five or six days, then a dose every second day. No disagreeable local or constitutional symptoms follow either the intravenous or muscular injections. Hydroquinin has been used both intravenously and intramuscularly as a prophylactic with satisfactory results.

From the close study of his own series, as well as many cases seen in consultation in which the vaccine treatment has been used, Graham is convinced that it is a distinct addition to treatment, and is also of more or less use as a prophylactic. In a case of moderate severity in either an infant or an older child, when the number of the paroxysms is small and of a mild character, the vaccine treatment is not necessary, but is often of distinct benefit, in the severe cases, in children of all ages, and its influence as a prophylactic, especially in which infants have been exposed, or in which a frail or possibly tuberculous child has been infected with the pertussis bacillus, should be carefully worked out, and its prophylactic power tested by its use, in a large number of cases.

10. Vaccine Treatment of Whooping Cough.—A review of the literature by Hartshorn and Moeller shows that 1,445 cases have been reported. There is not an universal endorsement of pertussis vaccine. A variety of vaccines are being used without definite knowledge of the bacteriology of the individual cases treated. There is a striking lack of negative reports. Apparently the vaccine is harmless in uncomplicated cases. There has been established no definite standard for dosage or for treatment. The dosage generally has been apparently too small. The course of the disease in the majority of cases reported has not been much under six weeks. Its value as a prophylactic agent is still undetermined. It is generally conceded that the earlier the treatment is given the better the result. The vaccine treatment is worthy of a more extensive trial.

The authors have treated eighteen cases of pertussis with vaccine. They conclude that a certain number of cases will respond favorably to a commercial vaccine. Where a commercial vaccine has not proved successful it would seem desirable to try an autogenous vaccine. The initial dose should be at least 50,000,000 in older children, and this may be doubled at subsequent treatments up to 40,000,000 at five days intervals. Further observations regarding dosage indispensable. A certain number of cases will not respond favorably to a vaccine, and in those it should be continued after a trial of 4 doses. The relative value of the combined vaccine as compared to the single culture vaccine is undetermined. In that the improvement in a few cases was immediate and striking, it seems fair to the authors to suggest but not to recommend, its use.

11. Blood-Serum of Immunes in Malignant Scarlatina.—Barker cites four cases with three recoveries and endorses this method of treatment. As described in one case the procedure adopted was as follows: At 10:30 p. m. (February 10) about $1\frac{3}{4}$ ounces of blood was extracted from the mother's arm. Allowing this to stand, after sterilizing with a little boric acid they were able to secure next morning $1\frac{1}{2}$ drams of supernatant serum, which was injected hypodermically in the child at 10:40 a. m. (February 11). This injection of serum was repeated evening and morning until 4 injections, each between $1\frac{1}{2}$ and 2 drams, were given. The condition of the patient at the time of the blood-serum injection was at its worst—in fact it would have been hard to conceive of how it could have been worse. For twelve hours thereafter no change could be noted. Then it first became

evident that not only was the case not retrograding, but slightly ameliorating. The cold baths were followed by not so rapid and marked return of hyperpyrexia, dyspnea was less agonizing, the reflexes formerly abolished began to assert themselves and coma grew less profound. This improvement by twenty-four hours, after the first injection was very manifest and continued progressively to convalescence. What was worth noting also in the case was the fact that aural and cervical sequela were absent, although both adenitis and otitis of no mild type had been present.

25. Paralysis Agitans Syndrome with Syphilis.—A study of the spinal fluid of cases of paralysis agitans has been made by Camp. In ten cases, typical in all respects, it was normal. The cell count in all cases averaged under four, the globulin and albumin were not increased and reducing substance was present. Six of these patients received intravenous injections of neosalvarsan. One patient, age 45, having the disease about two years claimed that the tremor was lessened that his appetite was better and he had less stiffness; objectively, there was a slight lessening of the rigidity but the characteristic tremor persisted. In two other cases there was an improvement subjectively but no objective change. One patient developed severe nausea and vomiting after the second injection and refused further treatment. In two the treatment had no effect whatever. Camp states that a typical Parkinson syndrome may coexist with and be caused by a syphilitic lesion in the central nervous system but that this is not the etiology of the disease paralysis agitans and, furthermore, that any lesion in the central nervous system causing a Parkinson syndrome is likely an irritative rather than destructive one.

26. Epilepsy Chiefly from Roentgenologic Standpoint.—Ninety-five cases have been studied by the authors. Seven of these cases were found to be pituitary tumors, and in only one of these was there any other evidence of involvement of the pituitary gland aside from the epileptic attacks. In these tumor cases there was no local bony thickening at the base of the skull, in fact local thinning of the body of the sphenoid or the clinoid processes from pressure was found almost constantly. In sixteen cases there was local thickening of bony tissue that was confined to enlargement alone of the clinoid processes, or to thickening in the anterior fossa of the base of the skull. In 22 cases the local bony change was found in two situations, namely, the clinoid processes and the base of the anterior fossa. In 35 cases there were bony changes in three situations, namely, the clinoid processes, the

anterior fossa and the body of the sphenoid bone. In these cases there is an appearance of thickening along the entire base of the skull. In 15 cases no bony alterations were found.

An analysis of these latter cases shows that six gave clinical evidence of being cerebropathies; two gave clinical evidence of being paresis. One case showed a calcareous degeneration in the center of the pituitary region. One case showed on the roentgenogram that it was a case of internal hydrocephalus. In one case the picture was taken one week after the first attack. In another case, six months after the first attack. The three remaining cases had been epileptic from three to five years with infrequent attacks.

In the first class of cases, namely, in which the clinoids alone were involved or the base of the anterior fossa alone was involved, the average length of time of the existence of the epilepsy was five and a half years. In these cases 14 per cent. showed frequent attacks, as often as once in two weeks. In the second class of cases, namely, with changes in the clinoid processes and the base of the anterior fossa, the average length of time of existence of the epilepsy was seven and a third years. Twenty-five per cent. of these cases had frequent attacks. In the third class, namely, with changes in three places, the average length of time of existence of the epilepsy was four and two-third years. Sixty-six and $\frac{2}{3}$ per cent. of these cases had frequent attacks. It would seem evident, therefore, that frequency of attacks has more to do with producing local bony changes than the length of time of existence of the epilepsy. Age does not appear to signify as far as bony changes are concerned. For instance, 1 patient, 5 years of age, exhibited all the features, whereas 1 patient, 56 years of age, showed only one feature.

In the examination of an equal number of roentgenograms in which there was no history of epilepsy, 4 were found with marked clinoids, 2 with a thick anterior fossa, 2 with two features and 1 with three features, about 10 per cent. of alteration, whereas leaving out the cases of tumor the percentage of bony changes found in the epileptics is 80. Only 2 plates showed the three features markedly in cases in which there was no history of epilepsy. It would seem probable from these observations, that the bony changes in epileptics are found only in the so-called essential or idiopathic epilepsy. To sum up: The authors found a condition of local acromegaly in essential epilepsy, which they believe can only be due to venous stasis. This stasis can only come in one way, namely, from pressure within the box-like structure that contains the pituitary gland. The evidence appears to be in favor of a crippling of this gland by pressure. Hypopituitarism would consequently be the result. It is known that epilepsy accompanies this condition. Therefore, it would appear that so-called idiopathic or essential epilepsy is due to a mechanical injury of the pituitary gland.

41. Abderhalden's Syphilis Test.—On the basis of observations made in 75 cases, Varney and Morse claim that the specificity of the Abderhalden technic applies to syphilis. Syphilites have in their blood-serum enzymes which react with the protein of the organism. Tissue derived from active human lesions are more specific than syphilitic tissue of the rabbit. Mixed infection in the human lesion gives rise to error in mixed infections as shown in their cases of sinus disease, furunculosis, etc. Further work will be required to determine whether all syphilites have the power of developing ferment and at what stages of the disease the test is present or absent.

The authors believe that polyvalent antigens prepared from several stains of pure culture of the spirochetes offer the best hope for further success with this technic. The degree of the success with the test varies in proportion to the care and precision exercised in its execution. No matter how carefully the material is prepared or the test carried out, this method does not by any means approximate the Wassermann reaction for practical usefulness.

43. Use of Omentum in Abdominal Drainage.—Tucking the omentum around the infected area and securing by a stitch or two with fine gut, either to itself in such a way it will stay *in situ*, or often by putting a stitch from the omentum through the lower portion of the infected mass, being careful not to puncture into an abscess cavity, is the safeguard adopted by Ramsdell. When the omentum is not available he often uses the parietal peritoneum in the same way, so that any free pus that may be liberated will lodge outside the abdominal cavity. The procedure protects the rest of the abdominal cavity from free pus which would result in general peritonitis or secondary abscesses. It requires less packing and handling of bowels, which is always desirable. It requires a smaller incision and assures better and quicker drainage. It does away with too large a drain and localizes any secondary hemorrhage. It causes less liability to the formation of undesirable adhesions which would later cause functional disturbances.

71. Fate of Transplanted Bone.—Basing his observations on a large number of experiments, Phemister states that osteogenesis in bone repair occurs from the inner layer of the periosteum, from the endosteum, and to a much less extent from bone-cells and the fibrous content of the haversian canals. Viability of the cells of the transplant is dependent largely on their ability to get nutrition and to some extent on their degree of cell specialization. Periosteum and endosteum, being superficially located, receive sufficient nutrition to survive and proliferate. The great mass of bone-cells being away from the surface and surrounded by an extensive and difficultly permeable calcified matrix gradually undergo necrosis and absorption. A few about the periphery and lining the larger vascular spaces as well as the fibrous elements of the latter may survive and proliferate. Blood-forming cells of the marrow, despite their favorable nutrition and probably because of their greater degree of specialization, gradually undergo necrosis. The subsequent changes which the transplant undergoes depend on its composition and location.

Transplantation into a bony defect: Functional demand stimulates the surviving cells of the transplant to osteogenesis. Callus forms at either end which helps unite the transplant and the fragment. Creeping substitution of the dead cortex gradually occurs by the ingrowth of capillaries with dilatation of the haversian and Volkmann's canals, absorption of the old bone, and deposition of new bone in its place. When periosteum and endosteum are left on, the

transplant contains the greatest number of living osteogenic cells. Consequently, union between the ends and substitution of the dead cortex occurs most constantly and rapidly. When periosteum is removed, osteogenesis producing union and substitution occurs from the endosteum and few surviving cells of the cortex, but the process is much slower than when periosteum is left on. When both periosteum and endosteum are removed, new bone formation from the few surviving cells is slight, and union with the ends of the fragments and substitution of the dead bone are very much delayed. If such a transplant is cut into small pieces before implantation more cells survive because of the increase in surface and facilities for nutrition and greater functional irritation. Consequently, considerable callus forms from each piece and, fusing with that from the others and from the ends of the shaft, rapidly restores the continuity of the shaft. Ossification of the callus proceeds from the surface of each piece and substitution of their dead portions gradually occurs. Periosteum transplanted into ulnar defects and in subperiosteal ulnar resection failed to regenerate bone and restore the shaft, but in subperiosteal resections with reimplantation of cortex either alive or after boiling it formed a layer of callus about the reimplanted portion. Subperiosteal resection of the humeral shaft in the young was followed by regeneration of the shaft. Periosteum gets its chief impulse for osteogenesis not from any injury to itself but from the injured bone to which it is attached or intimately related and which demands repair.

Transplantation into soft parts: The same portions survive as in a bony defect but since there is no functional demand for bone in this location little proliferation or substitution occurs and the transplant is gradually absorbed. Transplanted periosteum produces little or no new bone for the same reason. The presence of an infection, if severe, results in death and failure of the transplant; if mild, there is set up in it an osteomyelitis with excessive proliferation and absorptive changes, but the transplant takes and is functionally a success. The details of all the experiments are given by Phemister.

77. Origin and Nature of Fetal Movements.—All Graham's experiments were made with guinea-pig far advanced in pregnancy. The method adopted for direct observation of the fetal movements has been opening the uterus but leaving the membranes and placenta attachment undisturbed. The methods used to produce asphyxia of the fetus have been: (1) ligation of uterine vessels, (2) occlusion of the trachea of the mother, (3) direct inhalation of CO₂ by the mother. In all the experiments which involved opening of the abdomen a light ether anesthesia was maintained throughout; and the animals were killed with ether at the close of the experiments without being allowed to regain consciousness.

Graham found that asphyxia of the fetus of sufficient grade will result in the production of fetal movements, more or less severe. The movements thus produced vary from mere attempts at respiration, sometimes resembling the fetal hiccup of Mermann, to more muscular contractions, simulating the general convulsions of CO₂ poisoning seen in the adult. At times these are sufficiently violent to be seen through the abdominal wall as distinct shocks. All of the generally recognized varieties of fetal movements, except those concerned with swallowing and sucking, have been produced experimentally by methods which induced an asphyxia of the fetus. The intra-uterine respiratory efforts are not accompanied by an aspiration of any appreciable quantity of fluid into the lungs and hence are not incompatible with life after birth. The explanation of this is not clear, but probably the contact of the skin with the air is an important factor in opening up the respiratory passages. The hypothetical intra-uterine rhythmic respiratory movements of Ahlfeld (*physiologische intra-uterine Athmungsbewegungen*) were not observed. The suggestion is made that the various active movements of the fetus experienced by many pregnant women in the latter part of pregnancy are expressions of a more or less severe, but usually transient, asphyxia of the fetus.

80. Inguinal Lipomata.—Of 154 herniotomies performed by Speed, lipomata were found present in the opened canal 73 times, giving a percentage of 47.4.

84. *Gonococcus Complement-Fixation Test*.—Reviewing the results of their work to date with especial reference to a study of specific versus non-specific antigens to be reported in detail in a later communication, the authors have deduced the following facts: 1. Very rarely have polyvalent antigens prepared from meningococci, pneumococci, streptococci, staphylococci, colon bacilli or cornybaacteria sufficed to fix complement. This does not jeopardize the specificity of the gonococcus antigen, since it is explained on the basis of supervention of a mixed infection. 2. In 10 per cent. of serums examined a weakly positive result was obtained with polyvalent *Micrococcus catarrhalis* antigen; in these cases the reaction was much more marked with the various gonococci antigens. Thus it may be inferred that the association between the gonococcus and the *M. catarrhalis* is not positively and absolutely defined; and it is not unlikely, on the other hand, that a culture of the *M. catarrhalis* is occasionally included in a supposedly specific polyvalent gonococcus antigen, while on the other it is undoubtedly true that a mixed infection, often due to the *M. catarrhalis*, exists in patients suffering from gonorrhea and its complications.

3. A negative gonococcus fixation test does not necessarily mean that the patient is not infected with the gonococcus; in a primary uncomplicated acute case the authors have never observed a positive reaction prior to the sixth week, nor have they obtained positive reactions in which the anterior urethra or vagina alone were involved. 4. A positive result apparently is more specific than the Wassermann reaction, since thus far the authors have found no disease other than gonorrheal in which a positive result was obtained. 5. A positive reaction has been discovered in 21 per cent. of patients supposedly clinically cured; such patients, therefore, should not be discharged from treatment or observation until a negative response is obtained, provided the patient has not been the recipient of immunotherapy. Thirty-three per cent. to 75 per cent. of patients with chronic posterior urethritis, prostatitis, and seminal vesiculitis, with recurrent exacerbations, demonstrate a positive reaction. Sixty-six per cent. of all stricture cases have shown a positive result. 8. Approximately 100 per cent. of cases of active epididymitis or arthritis, at least by the fifth week, have demonstrated a positive gonococcus complement-fixation reaction. The test has proved of value in gynecology in the differential diagnosis of various pelvic inflammatory diseases from one another and from neoplastic formations; also in the differentiation of certain acute and chronic arthritides. Sociologically, the gonococcus complement-fixation test seems destined, along with the Wassermann, to play an important rôle in the future in determining the matrimonial fitness of candidates.

86. Roentgen Diagnosis of Duodenal Ulcer.—Of 82 operated cases of duodenal ulcer an exact diagnosis was made by George and Gerber in 78 cases. In 3 cases duodenal ulcer was reported, but there were minor errors and diagnosis. In 1 case there was a complete failure of diagnosis. Of 150 patients operated on in whom a negative roentgen diagnosis was made, duodenal ulcer was not found in any case. In 1 necropsy a duodenal ulcer was found, in which the previous report had been negative.

89. Woven Catgut Splints for Treatment of Fractures.—Straus uses catgut woven in the form of a rug with long fringed ends, the rug to be just a little shorter than the circumference of the bone, and the fringed ends to be used to tie the rug about the bone as a splint. These ends when tightly tied stretch the rug about the bone, holding it firmly in place. The idea has been carried out in a number of experiments on dogs. The splints have been made of rough German catgut No. 4 and No. 5. The raw gut has been given to an expert oriental rug weaver, who weaves it on a hand-loom, the gut being wet during the process of weaving to soften it so that it is possible to make a very

closely woven rug. The rugs are long enough to encircle the femur of a large dog, and are so woven that the length of the rug can easily be reduced to exactly fit any bone of a smaller circumference. This is of great practical importance and is accomplished by having the strands that run the long way of the rug (the warp) consist of separate fibers, while the cross fibers of the rug (the woof) are made of one long, continuous strand of gut which is alternately woven over and under the long parallel strands. To shorten the rug, to fit any given bone, it is only necessary to cut one end of this cross-strand free, unravel a sufficient amount, and then tie the free end again. Thus in human work it would be necessary to have only two sizes of rugs, one for large bones (femur, humerus) and one for small bones (radius, ulna). When the finished rug is dry it is cut from the loom and is ready to be sterilized. This has been done by the Bartlett iodine method only.

The bone ends are exposed by a free linear incision and the muscles gently separated from the bone; the catgut rug is then introduced around the bone, care being taken not to injure or displace the periosteum. Being sure that the line of fracture is at the center of the splint, begin tying the two opposite free ends of each of the longitudinal strands of the rug. If it seems desirable to reinforce the splint, the free ends after having been tied are long enough to make it possible, after having tied the first series of suture ends to carry the free ends around the tied splint and tie each pair of ends again over the original row of knots, so as to thus double the thickness of the splint. When all the strands have been tied and cut, the soft parts are united over the bone with No. 0 plain catgut, the fascia and skin each similarly closed, and the limb put up in a plaster cast, which is left in place for three or four weeks. The result in the ten dogs on which this procedure has been tried have been encouraging. However, with the splints as they have so far been used there is some interference with external callus formation, the only apparent external callus being just beyond either end of the splint in the form of a collar of callus; the internal and intermediary callus seem well developed. There have been three cases of non-union. One was due to local infection. The second was in a dog that died from an infected struma. The third was in a dog that contracted the mange and was killed. No trace of the splint is to be seen at the end of three weeks and no inflammatory reaction seems to be produced by the presence or absorption of the splint, except in a few cases in which a serous oozing occurred soon after the operation. This ceased shortly, however, and the healing was *per primam*.

8. Cytology of Blood in Passive Immunity.—Evidence is adduced by Douglas that in rabbits, as in man, the leukocytes are more numerous at 2 p. m. than at either 10 a. m. or in the evening, and that this is independent of the time of feeding. The increase in the number of leukocytes in man was proportionately the same at noon and at 3 p. m. when an artificial leukocytosis was produced. The introduction of horse-serum subcutaneously into man produces no change in the amount of hemoglobin or in the number of red cells, but produces a leukocytosis.

The injection of antitoxin in man produced no specific recognizable alteration in the cytology of the blood, the rate of the rise and of the fall in the leukocytes being the same whether a normal or an antitoxic serum was injected. The introduction of antimicrobial (antistreptococcic) serum was followed by an absence of any leukocytosis in the case of man. This probably depends on a failure of the body to respond with a leukocytosis to an injection of serum which follows a series of previous ones, each of which has succeeded in producing such a change, comparable to the failure in the power of antibody formation described by Axel Jørgensen after repeated daily inoculations of antigen, the two phenomena being possibly closely related.

The varieties of cells taking part in the leukocytosis as a response to serum injections in the case of man are (1) the polymorphonuclear and the eosinophilous group, and (2) the transitional and large mononuclear group, no change being demonstrable in (3) the lymphocyte group or (4) the mast cell group. No change could be detected in the hemoglobin percentage or in the numbers of red corpuscles in rabbits as the result of injecting rabbit-, goat- or horse-serums, whether normal or containing antibodies, by whatever route they were introduced.

No change could be demonstrated in the numbers of leukocytes in rabbits as a result of the introduction of rabbit- or goat-serums, whether normal or containing agglutinin, by whatever route they were injected, while a leukopenia may be found to follow the introduction of horse-serums, whether normal or containing antibodies. No evidence has been found that the antibodies as such have any influence on the cytology of normal blood in the case of either man or rabbits.

9. Excretion of Urinary Solids.—Kinloch found that a typical diminution in the quantity of urine occurs in the glomerular nephritis of scarlet fever and diphtheria, and this diminution is present at the very commencement of nephritis. In the pure forms of interstitial nephritis in scarlet fever and diphtheria, no diminution of urine occurs other than can be explained by the elimination of an extra amount of water by the lungs and skin in the presence of pyrexia. In the glomerular nephritis of scarlet fever, nitrogen is diminished both in percentage constitution and in daily output during the acute period of the illness. In the glomerular nephritis of diphtheria, no initial percentage diminution occurs. In the interstitial nephritis of scarlet fever and diphtheria,

nitrogen is freely eliminated from the onset, and this continues throughout the nephritis.

An immediate and long-continued diminution of chlorin occurs in glomerular nephritis in scarlet fever. The elimination of chlorin is free and regular in the interstitial nephritis of scarlet fever. A diminution of chlorin occurs at the onset of glomerular nephritis in diphtheria, and with the early diuresis the chlorin output is at once increased. The output of chlorin is free in the interstitial nephritis of diphtheria when uninfluenced by diet or pyrexia.

The daily output of phosphorus in the whole series of cases is commonly low. No general ratio between the output of nitrogen and sulphur can be determined. In the glomerular nephritis of scarlet fever and diphtheria the daily output of ethereal sulphates is commonly large in the acute stage of the nephritis.

The examination of the urine in various forms of nephritis indicates certain functions of the kidney. The glomerulus normally passes out by far the greater part of the water of the urine. This action of the glomerulus is in great part destroyed in glomerular nephritis. The glomerulus may excrete a larger proportion of nitrogen than has hitherto been assumed. This would explain the diminished nitrogen percentage and daily output in the acute period of glomerular nephritis in scarlet fever in which the glomerular lesion is extensive. The retention of nitrogen might, however, be explained by supposing that it is dependent on secondary body changes resulting from the renal disease. A special secretory function is to be attributed to the glomerular epithelium in order to explain the excretion of chlorids. This is well shown in the glomerular nephritis of scarlet fever, in which the diminished chlorid phase continues in the presence of free urinary excretion, with augmented diet, and in the absence of pyrexia. The excretion of chlorids follows a definite course in each type of nephritis.

The glomerulus appears to have little effect on the excretion of phosphates. With increased diuresis in glomerular nephritis the percentage of phosphates in the urine tends to be diminished, and the total daily output tends to be increased. The glomerulus excretes sulphates independently of the excretion of nitrogen. This is found early in the glomerular nephritis of scarlet fever in which a high percentage of sulphur accompanies a low percentage of nitrogen. In cases of nephritis in which nitrogen is freely eliminated from the first, a high sulphur output accompanies the high nitrogen excretion. The excretion of nitrogen appears to be unaffected by the degenerative changes found in the tubular epithelium.

Reabsorption of chlorids in the renal tubules does not explain all the variations of chlorid excretion. The lesions found in the cells of the convoluted tubules in interstitial or glomerular nephritis do not appear to influence the excretion of phosphates. Any reabsorption in the renal tubules has not been shown definitely to influence the percentage or total daily output of phosphates and sulphates.

Lancet, London

- 13 *Diagnostic Value of Complement Fixation Reaction in Tuberculosis. J. McIntosh, P. Fildes and J. A. D. Radcliffe.
- 14 Sepsis in Recognition and Non-Recognition of Syphilis. E. M. Corner.
- 15 Importance of Very Thorough Examination in Cases of Foreign Body Alleged to Have Been Swallowed or Inhaled. E. D. Davis.
- 16 Case of Congenital Atresia of Bile-Ducts. S. Wyard.

13. Complement Fixation Reaction in Tuberculosis.—The technic employed by the authors in carrying out the tests resembles in principle that elaborated for the Wassermann reaction. As an indicator they used both sheep and ox corpuscles, and found the latter to be of advantage when the test serum contains an excess of the so-called "normal amboceptor" for sheep's corpuscles. Further, they allow one and one-half hours instead of one hour as in the Wassermann reaction for fixation to occur. The antigen was a simple emulsion of living tubercle bacilli. The strain

employed in the tests was of the human type isolated from a case of phthisis, and was grown on Dorset's egg medium.

Group 1. "Pathologically certain" cases: In this group are included only those cases of tuberculosis in which there was definite histologic or bacteriologic evidence of tubercle. An analysis of 85 cases gives the following results: Phthisis, 43 cases, 33 positive, 76.7 percentage, surgical tuberculosis (with the exception of tuberculous glands), 26 cases, 21 positive, 80.7 percentage, tuberculous glands, 16 cases, 6 positive, 37.5 percentage. Group 2. "Clinically certain" cases: In this series the diagnosis of tuberculosis rests on clinical examination only, as opposed to bacteriologic or histologic. In this series the results were as follows: Phthisis and pleurisy, 18 cases, 10 positive, 55.5 per cent., surgical, 42 cases, 30 positive, 71.4 per cent. Group 3. Tentative cases: The serums of 74 cases in which the diagnosis of tubercle was purely tentative were examined, and of these 18 were positive. The positive results included cases of pulmonary fibrosis, pleurisy, enlarged cervical glands, ulceration of bladder, synovitis, persistent pyrexia, etc. Group 4. Controls: The control cases, 87 in number, were taken without any selection and included a great variety of disease conditions in addition to normal individuals. All were negative with the exception of 3 cases, these being 2 cases of leprosy and 1 of Addison's disease. The serums of 18 syphilitic patients with positive Wassermann reactions were tested and all reacted negatively. In the face of these controls the reaction is regarded as being highly specific.

- 24 *Functioning of Gastro-Enterostomy Opening with Permeable Pylorus. (Les bouches gastro-intestinales dans le cas de pylore perméable.) H. Hartmann.
- 25 *Fatal Acute Ulcerative Colitis. C. Flandin.
- 26 *Treatment of Hemorrhagic Rectocolitis with Tendency to Erosions. G. Friedel.

24. Gastro-Enterostomy Opening with Permeable Pylorus.—Hartmann reports a number of experiments on dogs and the roentgenoscopic findings in nineteen patients after gastro-enterostomy. In all the clinical cases the motor functioning of the stomach had not been impaired and no evidence of stenosis of the pylorus had been found at the operation. Recently reexamined after an interval ranging from one to eleven years, it was found that all the stomach content was evacuated through the pylorus in one case, and all through the artificial opening in eleven; in the others part passed through each opening. These clinical experiences confirm his experimental conclusion that the fact that the pylorus is and remains permeable does not inevitably render the artificial opening useless. A gastro-enterostomy in the antrum of a permeable pylorus amounts to the physiologic exclusion of the pylorus and the duodenum. But when the artificial opening is made nearer the cardia, in the reservoir part of the stomach, then this opening is useless for evacuation of stomach contents if the pylorus is permeable.

25. Acute Fulminating Colitis.—Flandin's patient was a previously healthy woman of 44 taken suddenly with acute dysenteriform colitis, fatal in less than four weeks, during which her sufferings were extreme. Some improvement followed exclusion of the large intestine, an artificial anus having been made in the small intestine, but the condition already was beyond repair and fatal perforation soon followed. The course is usually rapid and menacing in these cases of acute ulcerative colitis. Mummery has compiled eighty cases with 50 per cent. mortality.

26. Hemorrhagic Rectocolitis.—Friedel refers to cases in which there does not seem to be any ulceration and the blood gathers on the walls of the bowel like the sweat on the brow. There seem to be minute erosions, scattered or confluent, and the bleeding occurs at these points. He describes nine cases in detail. Hemorrhagic colitis of this type develops with intervals of apparent health; after fifteen or twenty days of diarrhea and hemorrhages all seems to return to normal. With cancer in this region there is usually less loss of blood at one time but the slight hemorrhage keeps up continuously. Treatment should act on the colitis and the rectitis, healing the erosions and supplementing or correcting insufficient gastric digestion or other dyspepsia by appropriate measures. Water and oil, he says, are seldom tolerated by the rectum but a mucilaginous vehicle is tolerated and acts as a kind of dressing for the inflamed mucosa. Surgical treatment is a comparatively serious matter and the outcome is not always satisfactory, while it entails danger of a permanent fistula. Medical measures, on the other hand, have always given him good results, while the technic is simple, easy and within the reach of all.

- 28 Fracture of Bones and Wounds of Joints during Balkan War. Laurent.

27. Ankylosis of the Knee of Gonococcal Origin.—Okinczyc deplores the too frequent custom of publishing cases before a decisive judgment on the outcome of operative treatment is possible, and the tendency to publish only the favorable cases. He recently encountered a man whose stiff knee had been resected a few months before with interposition of a flap of aponeurosis, but the knee is now stiff again. He has been able to find only eighteen cases on record of operative treatment of ankylosis of the knee of gonococcal origin, including Murphy's two cases, and the ultimate outcome is known in only five. Even in these the results of treatment were generally poor, so that there is little evidence to encourage operative interference unless the knee is severely crippled by the ankylosis or when both knees are affected, or, with incomplete ankylosis, there is pain when the leg is used. On the whole, it is much safer to respect a solid ankylosis and not to try to restore functioning to the knee. The gonococcal process is peculiarly prone to recur as the lesion usually extends into the tissues around the joint. Payr waited a year after the last symptoms before operating and then removed the capsule, ligaments, and fibrous tissue around the joint, leaving the musculature intact, and interposing pedunculated flaps of aponeurosis lined with cellular-fat tissue from the vicinity, and he has reported perfect functioning of the knee two years after the operation at two sittings, seven weeks apart. In his two other cases, with less extensive operations, the ankylosis has recurred in one. Okinczyc cites in conclusion two cases successfully treated by Morestin with arthrectomy to insure firm ankylosis after failure of various other measures.

35. Auscultation Findings with Heart-Block.—Clarac and Pezzi regard as most important the appearance now and then of a reinforced explosive first sound whenever it happens that the auricle and ventricle contract together; that is, when the systole of the auricle coincides with the first part of the contraction of the ventricle. This occasional explosive first sound always testifies to total heart-block if the ventricle beat is regular. Other significant auscultation findings are a systolic murmur at the mitral and tricuspid orifices, and also faint, dull, brief auricle sounds during the diastole, heard as the patient holds his breath.

Semaine Médicale, Paris

- 36 *Serodiagnosis of Syphilis by the Coagulo-Reaction. L. Hirschfeld and R. Klinger.

36. Serodiagnosis of Syphilis by the Coagulo-Reaction.—Hirschfeld and Klinger call attention to an inhibition of coagulation which seems to be specific to syphilitic serum alone. Coagulation is the result of precipitation of the fibrinogen in the plasma by the thrombin. The thrombin itself is the product of the interaction of a serozyme (an albuminoid), a cytozyme (a lipid), and a calcium ion. The organ extracts used for the Wassermann test represent an active cytozyme and this property is not affected by normal serum; coagulation occurs with them whether normal serum is added to them or not. But addition of syphilitic serum arrests all coagulation. This is the principle of the new test, the inhibition of coagulation in oxalated beef blood-plasma when syphilitic serum has been added to the organ extract previously diluted with rabbit or other serum and a 1 per cent. solution of calcium in physiologic salt solution. The findings with this coagulation test in 750 cases paralleled those of the Wassermann test except that the coagulo-reaction seemed perhaps a little more sensitive.

38. General Anesthesia for the Badly Frightened.—Scholz refers to patients whose dread of the operation is worse for them than the operation itself. The mere entering the hospital and the preparations frighten them. Whatever the cause, their fright may be so intense that the anesthetic actually fails of its effect at first. They may conceal their dread but it is generally revealed by some sign on the part of the vasomotor and visceral innervation, which is peculiarly unstable in patients of this category. They are inclined to tachycardia, false angina pectoris, polyuria, glycosuria, nervous diarrhea, transient numbness, angioneurotic edema, shallow, rapid breathing with occasional deep breaths, tremor, pallor and dryness of the mouth. Carbon dioxid seems to be a special product of extreme dread.

Scholz has been making a special study of the influence of the above factors on the action of general anesthetics. The blood-pressure in such patients suffered a constant and regular decline as the ether or chloroform was administered, until consciousness was entirely lost. The average drop in sixteen cases was 44 mm. mercury in fifteen minutes. In one case the decline was 69 mm. In such a condition of low blood-pressure the patient is exposed to various dangerous reflex processes, especially to reflex syncope from irritation by the anesthetic of the terminals of the trigeminus in the nose, the reflex action from this involving the vagus terminals in the heart and the respiration center in the medulla. Rosenberg has found that this reflex can be warded off by cocainizing the nose. The fatalities as general anesthesia is just commenced are undoubtedly due to this dangerous reflex, although they are usually ascribed to an "idiosyncrasy to the chloroform or ether." The action of the reflex is exaggerated further by the abnormally small amount of carbon dioxid supplied to the respiration center owing to the shallow and fluctuating breathing, as Henderson has explained.

Another important reflex is shown in the extreme dilatation of the pupil from the first moment of the anesthesia, and its persisting thus instead of gradually contracting under the influence of chloroform. This should be regarded under all circumstances as a sign of a menacing idiosyncrasy to chloroform. He has encountered two such cases this year; in one, under 3 gm. of chloroform and 25 gm. of ether given with extreme caution, the appendix was removed without mishap from the badly frightened boy of 12; the other patient, a much-excited man of 32, had a profound collapse. Scholz regards this symptom as the only one which points from the very first to impending danger. Another set of reflex symptoms are like those noticed in a person who has fainted from fright. They can be brought on by forcibly holding the patient, pressing down the inhal-

ing mask, or other procedure that frightens him. These symptoms occur mostly in young, half-grown patients whose hearts are especially liable to fail under sudden fluctuations in blood-pressure.

Still another set of reflexes may be elicited from the abdomen if the operation is commenced before all reflex action is abolished. In a very nervous woman of 32 the blood-pressure dropped from 152 to 87 in fifteen minutes. The chloroform was then dropped and ether given and the blood-pressure went up. Eight minutes later, in profound anesthesia with blood-pressure of 110 mm., the peritoneum was incised and the appendix drawn out. The blood-pressure dropped as this was done to 75, a minute later to 66, and then to 62 mm. The anesthetic was then discontinued and the pressure rose to 77 mm. and the appendix was removed without mishap. If the heart had been less able to stand the strain in this case, there might have been a fatality. The trouble was probably a sudden relaxation of the tonus of the vessels of the viscera superposed on the injury already inflicted on the heart by the toxic action of the anesthetic. This last set of symptoms includes the reflexes elicited by abrupt changes of position. Scholz gives a number of roentgenograms of anesthetized dogs first reclining and then suspended with the head down, showing the remarkable displacement of the diaphragm possible in these conditions, and the resulting obstruction to the pumping action of the heart. In his two most serious clinical cases of collapse from change of position under general anesthesia the patient was in a dentist's chair.

He expatiates further on the remarkably long persistence of the reflexes in extremely frightened patients. Even after the corneal reflex is abolished, the pulse fluctuates with every tug at the viscera, and the anesthesia has to be made deeper. This encroaches on the margin of safety, and extreme care is necessary to give the anesthetic as regularly as possible and not to allow any wavering between the arousing of the reflexes and syncope. After the reflexes are abolished there may be collapse from overdosage, but this is always ushered in by a disturbance in the breathing—any change from the tranquil deep breathing is a signal for stopping the anesthetic. When tranquil deep breathing is restored, the anesthetic can be resumed. The whole secret is to tranquillize the patient, avoid anything suggesting force, and refrain from beginning to operate too early. Persons with an exceptional dread of the operation are exposed to peculiar dangers at the first whiffs of the anesthetic.

40. Tetany after Operations for Goiter.—Wiebrecht urges to refrain from injuring the parathyroids in operating on the thyroid. If tetany develops, he advises the implanting of fresh human parathyroid gland tissue or administering horse or beef parathyroids by the mouth. If neither of the above is practicable, parathyroid tablets might be given, along with calcium lactate. Curschmann advocates giving 20 drops of a 10 per cent. solution three times a day, gradually increasing the dose until the patient is taking several teaspoonfuls daily.

42. Operative Treatment of Epilepsy.—Weispfenning reviews the experiences in this line in Kümmell's service, a total of 31 cases of epilepsy without known trauma, 11 of traumatic epilepsy, and 2 of the Jacksonian type. Of 26 true epileptics, 11 per cent. were cured and 10 per cent. materially improved. Transient improvement was noted in 4 of the 13 listed as unmodified by the operation. In 11 of them the epilepsy was of long standing—in 7 over nine years. In the 11 traumatic epilepsy cases only one patient was cured and one improved. One of these patients developed general epileptic seizures for the first time after a large defect in the skull had been closed with a celluloid plate. The intervals were at first only four weeks but have been growing much longer and the seizures much milder.

45. Cancer of the Lower Esophagus.—Hauch gives an illustrated description of eighteen cases of cancer in the middle and lower esophagus in which he succeeded in removing the growth. One patient succumbed to a recurrence a year after successful resection of the cancer in the

lower esophagus and cardia. None of the other patients survived the operation or the following few days. The operative shock was evidently too great, possibly from the very efforts to shorten the operation.

46. Operation for Ruptured Aneurysm of the Aorta.—The man of 52 succumbed to heart weakness a few hours after Kummell had sutured the aorta after cutting and remodeling the artery so that it approximated the normal size. The circulation was shut off for twelve minutes by compression with the fingers and was then gradually released. The suture held perfectly and the patient was in good condition after the hour operation. It was done under intravenous ether anesthesia, keeping the heart action good with saline and ether. The previous loss of blood, however, had reduced the patient's strength so that he succumbed to gradual heart failure. The operation was done from the rear, resecting ribs (four to ten) and pushing the unopened pleura out of the way. This affords ample access to the intrathoracic esophagus and aorta. The aneurysm in this case was above the diaphragm.

48. Infection of Gunshot Wounds.—Kayser declares that modern experiences and science have reconciled theory and practice and shown that immobilization is the most powerful means at our command to ward off and fight sepsis. Fixation, he reiterates, is the key to success; fixation of the bacteria in the vicinity of the wound, and fixation of the dressings; fixation of broken limbs by supporting dressings, and fixation of the patient to his bed so that he will be transported on the one litter from the battle-field to his home. Bacteria are always with us, and the organism is generally able to cope with them if left unmolested and perfectly quiet.

51. Operations on the Stomach.—Roedelius reviews 312 operative cases in the last three years for gastric ulcer, cancer or other affection; resection was done in 43 cases and excision in 3, in 33 merely an exploratory laparotomy. The outcome was excellent as a rule in all but the 130 cases of cancer. Of 38 treated by resection, 39.5 per cent. have been clinically cured to date. The Roentgen rays were systematically applied in a large number of cases of malignant disease and although no benefit was apparent in many of the advanced cases, yet the unmistakable favorable effect in a few instances justifies further work in this line.

54. Why Patients Still Have Disturbances after Cholecystectomy.—Graff and Weinert sent question-blanks to 130 patients whose gall-bladder had been removed, inquiring as to their present condition. They had 124 blanks returned and 87 of the patients stated that the operation had cured them once and for all, and 4 others said that they had had no disturbances since the first month. That is to say, 73.4 per cent. had been permanently cured by the operation. About 78 patients mentioned that their previous tendency to constipation had been cured by the operation; stomach disturbances as a rule also subsided permanently afterward. In four cases attacks of pain and jaundice indicated that gall-stones had been left behind, but two had only a brief single attack and have been well since. In ten cases at least, adhesions are evidently responsible for the disturbances and the technic should be planned to ward-off production of adhesions. Subserous enucleation of the gall-bladder and roofing over the bed of the gall-bladder with peritoneum aid in preventing the development of adhesions, as also restricting tamponing to the minimum. If adhesions have already formed, the wounds left when they are broken up will give cause for still more adhesions to develop—another reason for operating early.

55. Gall-Stones.—Schulz regards the interference with the free circulation of bile during pregnancy as the chief cause for the development of gall-stones later. Not only mechanical, but chemical and other factors, aid in the process, including passive hyperemia, exaggerated destruction of red corpuscles and the toxic effect of fetal excrementitious matters. Among the 584 women in his 654 gall-stone operative cases in the last three years only twelve had not borne children among the 572 who were married. A tendency to

from 0.5 to 1.1 per 1,000 inhabitants since 1875. During this period the number of cases of malignant disease under the age of 20 has increased by 315 per cent.; between 20 and 50, by 246 per cent.; between 65 and 80, by 446.1 per cent.; and over 80, by 890.2 per cent. The proportion of cancer deaths to the total mortality has increased under the age of 20 from 0.43 to 2.05 per cent.; between 20 and 50, from about 24 to 77; between 50 and 65 from 82 to 216; between 65 and 80, from 38.12 to 147.40 and for over 80 from 11.02 to 54.55 per cent. The total increase in the proportion of cancer deaths to the mortality at large has been from 21.49 per cent. in 1875 to 81.37 per cent. in 1912. One fact stands out in his tables, namely, that the increase in cancer at all ages, except between 20 and 50, has been greater among men than among women. The increase in men between 20 and 50 has been from 2.09 to 3.4 per cent.; in women, from 3.13 to 4.26 per cent. for each 10,000 inhabitants.

101. **Recurrence of Gall-Stones after Operations.**—Lameris' case was apparently an instance of recurrence, as the woman's gall-bladder had been removed two years before and the bile duct carefully searched. The structure of the gall-stone found at the second operation, however, disproved the idea of recurrence, as the structure in the center unmistakably indicated that it was a calculus overlooked at the first operation, which had gradually enlarged by incrustation to its present size. The patient was a woman of 43 who had borne ten children.

102. **Inheritance of Color-Blindness.**—Waardenburg has noticed that the sex plays a part in the inheritance of color-blindness as it may be transmitted through normal daughters to grandsons. He urges physicians to investigate conditions in regard to heredity among the color-blind; whether the taint dies out, and whether when a woman is color-blind there was a familial tendency in both parents, also the different forms which the color-blindness may assume in different members of the family. He says that the first cases of color-blindness on record were in three brothers (Huddart, 1777), while the other children were normal. It is estimated that about 3 per cent. of all men are color-blind but only 0.25 per cent. in women.

103. **Starving Infants.**—De Lange refers to infants kept on rice water or barley water—possibly by a physician's orders—for some transient illness but which the mothers in their mistaken zeal continued long after the necessity for it had passed. The child is actually starving to death on this inadequate nourishment. De Lange has encountered twenty-four cases of the kind in the last two years, and she tabulates them in instructive fashion to show the present status; the exact causes; the measures applied, and the recovery under them; only four succumbed. De Lange remarks that she had never supposed there was any call in the Netherlands for an organization like the British Society for the Prevention of Cruelty to Children but since she has found two dozen infants thus starving to death, usually from blundering solicitude, she thinks there is certainly a call for reform. They resembled in appearance infants with relative acidosis from loss of water and salts—the condition which the Germans call "decomposition"—but the starved babies were not so apathetic and their livid tint was not so pronounced. Great caution is necessary at first in giving nourishment to an actually starving infant. Buttermilk renders good service here.

104. **Treatment of Paraphimosis.**—Van Cappellen injects into the edematous internal layer of the prepuce a weak solution of an anesthetic containing a little epinephrin. Under the influence of this the swelling subsides and the retraction of the foreskin can be readily overcome. He has applied this procedure in several cases and with constant satisfaction. The operation for the phimosis can then be done at leisure.

112 *To Render Finger Prints Visible. (Nuevos reactivos para la revelacion de huellas digitales invisibles.) Maestre and Lecha-Marzo.

107. **Toxic Neuroretinitis and Iridocyclitis.**—Argañaraz reported in 1912 six cases of severe optic neuritis following on the use of salvarsan; two were encountered in his own practice and the others were clients of other local physicians. He now reports a similar group of a severe toxic affection following the use of salvarsan or neosalvarsan, four in his own practice and three from the experience of other local physicians—the disturbances affecting the uveal tract and the sensory apparatus of the eye in these cases. The symptoms observed suggest a toxic action from the drug. In the cases in which the salvarsan was continued after they had developed—assuming that they were the work of spirochetes that had escaped the action of the salvarsan—the symptoms grew progressively worse as the drug was continued. One patient became blind and another suffered such intense pains that he pleaded to have his eye enucleated. The iridocyclochoroiditis became progressively worse with hemorrhages and secondary glaucoma, entailing the destruction of the eye. This fate also confronts another patient and no benefit has been derived from vigorous mercurial treatment. This young man had been given systematic mercurial treatment at the time he contracted syphilis, in 1912, and then was given two intravenous injections of salvarsan with an eight-day interval. Twelve days later his right eye developed iritis and he was given a systematic course of mercurial treatment, with iodid, but the serous iridocyclitis continued to progress, the iris became atrophied and adherent and vision from 1/4 had dropped to mere perception of outlines at about 7 inches. The further course in this case is not known.

In one of the group previously reported the syphilis was of fourteen years' standing, and had been kept under control with mercury. Then a single injection of salvarsan was given and bilateral optic neuritis developed at once, entailing almost total blindness. In conclusion Argañaraz cites from the literature various cases of amblyopia consequent on arsenical medication before salvarsan was discovered. The assumption that the eye affection in his cases would not have developed if the dosage had been adequate is disproved by two of the cases related in which the doses had been large and pushed after the first signs of trouble, the patient receiving six intravenous injections of neosalvarsan in four months, each of 0.9 gm. This is the patient, a man of 44, who begged to have the eye removed on account of the persisting pains; corneal sclerotomy was done twice and gave considerable relief.

109. **Gelatine Tampon after Operations on the Nose.**—Ferreyra injects about 10 gm. of a 10 per cent. gelatinized serum into the nose after an operation, having found that it spreads and rapidly hardens, forming an ideal tampon to arrest and prevent all hemorrhage. It leaves a passage open, while it is free from the danger of secondary hemorrhage later, such as is always to be feared when an ordinary tampon is removed.

112. **To Render Finger Prints Visible.**—More than twenty-one different methods for this purpose have been devised, but Maestre and Lecha-Marzo call attention to the superior value of zinc oxid to show up a finger print on a black background. For prints on paper, glass, etc., they recommend a mixture of iodine and eosin, heated until it vaporizes. The violet vapor then applied to the finger print brings out the lines very distinctly and permanently enough for the purpose. On paper, platinum black is even better. It has revealed finger prints not detectable by any other means in several criminal cases in their experience. Before anything is applied, the supposed finger print is photographed under oblique illumination.

CHONDRECTOMY OR OPERATIVE TREATMENT OF BRONCHIAL ASTHMA*

E. WYLLYS ANDREWS, M.D.

CHICAGO

The term "rigid dilatation" aptly defines a condition of the thorax wall often seen in old cases of emphysema and bronchial asthma. The bony, cartilaginous and muscular framework of this wall in young and normal subjects is united into an elastic lattice or basketwork, semirigid yet yielding, called very picturesquely by the Germans the basket of the chest (*Brustkorb*).

Functionally the thorax may be contrasted with the entirely rigid pelvis on the one hand and the non-rigid abdomen on the other, being intermediate in character—more flexible than the former and less flexible than the latter. Unlike the abdominal wall, which has powerful compression but only passive dilating power, the thorax wall has active expansion, creating negative pressure or suction and relatively little compressive force—chiefly passive.

In bronchial asthma and vesicular emphysema the chest becomes dilated or barrel-shaped and loses its power to contract when relaxed. The cartilages connecting the ribs to the sternum may take on a new hardness, due to partial ossification or calcification. They become asbestos-like and relatively firm and brittle in texture in some old patients, so that passive or elastic contraction of the chest is lost. The dilatation of the alveoli and lung tissue is so great that the chest wall remains fully expanded and the thorax loses nearly all power of lateral contraction. This produces or exaggerates the well-known symptom of expiratory dyspnea. Respiration must be carried on almost wholly by the diaphragm, which of itself has little control except over the inspiratory act. This is helped in part by the neck muscles which can fix and raise the clavicles and first rib, thereby lifting the whole thorax.

LOSS OF EXPANSION

In numerous cases examined in our clinic expansion was less than 1 cm., and in several it was nil, or too small to measure with the tape.

We owe what we know of the mechanical or surgical treatment of emphysema and apical tuberculosis to certain studies of a young Breslau physician over fifty years ago—1858. Freund, later a celebrated gynecologist at Strassburg developed this subject in eight papers from 1858 to 1910. These suggestions,

though published, lay almost unnoticed until after Listerism and the perfection of thoracic surgery, when he himself began to put his theories into practice and had the unusual satisfaction of seeing his technic adopted by Von den Velden, Garré, Hansemann and numerous other clinicians and freely credited as the Freund operation.

The term "Freund's operation" defines two distinct procedures, namely, the operation to relieve the barrel-shaped chest or rigid dilatation of old asthma and emphysema, and the operation to expand the upper outlet of the chest in certain types of apex tuberculosis. Both these operations, I am certain, have proved beneficial and even life-saving in my experience, but the latter—the one for emphysema—is of more practical importance so far in my work because more frequent.

MECHANICS AND PATHOLOGIC ANATOMY

Von den Velden, following Freund's classical work, shows the importance of defining clinically the various forms of rigid thorax, as the senile, or presenile, which is not in the form of dilatation or due to cartilage changes, the paralytic form and that due to kyphosis or rachitis, etc. The anatomic picture of rigid dilatation of asthma is peculiar and this form only is suitable for surgical treatment.

The essential feature is the calcification of the rib cartilages. They become bone-like and rigid, so that the chest wall cannot contract. Certain observers, as von Hansemann, take the rather extreme position that this bony condition rather than the asthma is the primary cause of the disease, the lung changes, such as thinning and atrophy of the alveolar walls, being secondary.

It is not necessary to believe this to admit the value of Freund's operation of chondrectomy. Surgical relief is possible in a certain type of these cases and ought promptly to be employed before dyspnea, cyanosis and too grave secondary changes have made all measures futile. I have found that these patients, usually old people with confirmed bronchial asthma and arteriosclerosis, nevertheless stand the interference remarkably well and are rapidly, almost instantly relieved, so as to be conscious of a betterment in their breathing and to show it in diminished cyanosis.

The method employed is a thoracoplasty which removes the costosternal joint and costal cartilages and substitutes a fibrous or hinge-like union of ribs to sternum, restoring at once full expansion to the thorax wall. Thoracic surgery has lost its terror, which was due largely to the dread that hangs about the unknown, and we no longer hesitate to open a pleural cavity without any cabinet or differential pressure. This operation need not endanger the pleura

* Read before the Section on Surgery, General and Abdominal, at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

or pericardium, although both are exposed, and does not, in my experience, cause any great amount of shock or present any serious technical difficulties.

REASONS FOR CHONDRECTOMY

It is the aim of the operator to detach from their sternal connections four of the ribs,—the second, third, fourth and fifth, and to make them permanently mobile by cutting out their cartilages. These four ribs are the only ones directly uniting the sternum, except the first, which will be referred to later. The diastasis of ribs from sternum is to be permanent. The intervening 3 or 4 cm. of non-rigid chest wall make a hinge joint to take the place of the excised hardened cartilages. Immediately after the operation there is more than a hinge action, a bellows or back-and-forth movement. The rib ends move longitudinally, alternately widening and narrowing the

The second, third, fourth and fifth costal cartilages are divided from the sternum and at or near the attachment to their rib ends. A little of the bony rib is best removed with each cartilage if the latter is short.

Unlike the Erstländer operation or ordinary rib-resection for carious rib or in empyema cases, in this operation the periosteum or perichondrium must be destroyed with the rib. This makes the dissection less easy, but not very tedious. In case of accidental puncture of the pleura no harm results. On its anterior surface, of course, this membrane comes easily with the rib; posteriorly, care must be taken by blunt dissection to make a line of cleavage between perichondrium and pleura, leaving the former intact on the cartilage. A spatula or Kocher director does this safely. Fragments of perichondrium seem prone to be left behind so that later more or less rigid cartilage reforms and makes the chest again inelastic. To prevent this I like to obliterate the groove left by each cartilage with a circular stitch of catgut. At least four other methods have been tested by followers of Freund in efforts to prevent this recurrence:

1. Hoffman sutures carefully the ends of the perichondrial tube over the stump of the cut-off rib, as is done in ordinary amputations through bone.

2. Axhausen applies the actual cautery to the remnants of these membranes in the grooves. This seems to me a grave danger to the adjacent pleura and lung and an obstacle to primary healing.

3. Bircher applies 95 per cent. phenol (carbolic acid) with the same intent. I have not tested this method.

4. Seidel uses slips or ribbons of adjacent muscles crossed like a letter X to fill the cavity between the rib end and the sternum. This I like very well, but find the lateral approximations of the groove just as effective.

A surprising feature of this work is the instantaneous relief obtained, not only after the operation but before its completion when the first cut through the cartilage is made. Instantly the chest wall expands and

contracts as it has not done for years and the gap in the rib opens and shuts with an excursion of 1 or 2 cm. As each section is made the expansion is increased, until when all four are divided they move apart and come together freely. In fact, the first relief is the best, and subsequent healing, as noted above, tends to impair the elasticity gained. In spite of the soreness of the incision the patient makes deep inspiratory and expiratory movements and his cyanosis disappears on the table. He can lie down as he has not done for years—resting his overstrained diaphragm and neck muscles which have been vainly trying to compensate for his reduced contraction.

WHEN CHONDRECTOMY IS CURATIVE

The proper selection of cases means success or failure of this as most other surgical operations. Not

Fig. 1.—Normal chest wall and form of pleural cavity (above) contrasted with rigidly dilated wall and cavity (below) as sketched by Freund, Garré and others.

Fig. 2.—Barrel-shaped cast of chest and normal chest (above); roentgenogram of cartilages before and after resection (below) after Sauerbruch.

space between their cut ends and the sternum. This is lost later as the space narrows in healing. It is even difficult to maintain the hinge action because the cartilages tend to grow again unless all traces of perichondrium are extirpated. Special means of preventing this are a part of the plan of operation.

TECHNIC OF CHONDRECTOMY

The operation is relatively simple to any one familiar with rib-resection in general. The pericardium is not exposed to injury in operating on the right side. Unilateral chondrectomy is usually sufficient to give relief. Bilateral operations are always done in two stages. A longitudinal or parasternal incision is more conservative in my experience. The operation can also be done equally well through four short transverse cuts parallel to the four ribs removed.

all asthmatics—not even all cases of emphysema—are to be so treated.

Only cases of rigid and dilated chest are helped by it. The diagnosis rests not alone on cough and dyspnea, but we have certain objective conditions of the thorax wall. It becomes cylindrical. The ribs assume

Fig. 3.—Relations (normal) of pericardium, pleura, rib and great vessels showing greater safety of chondrectomy on right side.

a more horizontal position than normal and do not sink in expiration. The sternum is pushed forward and the cartilages are bowed and rigid. This means that the lower thoracic outlet is enlarged. The epigastric angle is, therefore, widened from 100 to 140 degrees. Inspiration does not increase the chest cir-

Fig. 4.—Reflections of pleura in inspiration and expiration, showing extreme excursion.

circumference. Expiration is slow and stridulous. There is cyanosis and capillary venous stasis. The diaphragm is flattened and the right heart area is widened. Vital capacity is reduced from 3,000 or 4,000 c.c. (normal) to 2,500 or less; in extreme cases as low as 800 or even 400 c.c. (Franzenheim's case).

INDICATIONS AND CONTRA-INDICATIONS

To sum up our knowledge of this new therapeutic measure, the indication for its adoption is the presence of the emphysematous chest rigidly held in the "inspiratory position," that is, dilated. The operation restores the lost power to take the "expiratory position," that of contraction.

As contra-indications may be mentioned severe cardiac and vascular disease, fetid bronchitis or bronchiectasis. Lambert warns against Freund's operation in cases due to costo-vertebral ankylosis, in which it can do only harm. Also Mohr warns us to exclude two other types of rigid thorax: (1) cases of tonic rigidity due to abnormal tension of the inspiratory muscles in nervous and cardiac asthma; (2) cases of rigidity following paralytic chest wall.

WHAT MAY BE EXPECTED OF THE OPERATION

The true type for operation having been found—the barrel-shaped, rigid chest, with little or no expansion measured by the tape—much hope of relief is offered by chondrectomy. The operative mortality is almost nil. It is an operation very well suited to local anesthesia. With nerve-blocking of the intercostals it is absolutely painless. Relief begins when the first cartilage is cut through. It is an impressive sight to see the divided ends move freely in the wound where there had been no movement for years. Giving the stretched but still elastic lung tissue a chance to contract, we see that it proves its own elasticity after long overstrain. It is proper to remove the bony rib as well as the cartilage, if it seems to help the contraction. In one case I excised 6 cm. of the third and fourth ribs.

The diaphragm also acts more fully after the section, but in bad old cases we cannot always expect a perfect restoration of its cupola or dome, it having been flattened out by long stretching.

Vital capacity in good cases will be increased 50 or 100 per cent. Franzenheim reports one extraordinary

cross the front of the knee below the tubercle of the tibia. That bony prominence with the ligamentum patellae attached to it, is sawn off obliquely as in Sabanijew's amputation. The flap with the patella is then turned up. At the conclusion of the operation the tubercle of the patella is fastened to the tibia again. As with all these anterior horseshoe methods of arthrotomy, excellent exposure and access to the joint is obtained at the price paid for much division of soft parts at right angles to their line of action with consequent lengthening of the convalescence and increased postoperative disability. The position may be summed up by saying that transverse incisions in front of the joint are second-best, giving marked disability afterward from the necessary division of the soft parts.

Let us now consider longitudinal incisions, such as that of Professor Kocher, along the outer side of the patella. These are three in number: along the outer side of the patella, along the inner side of the patella and through a longitudinally split patella. Both of the lateral incisions are excellent, but, in my opinion, from their asymmetry they are not so efficient as the median incision and do not give so good a functional result as that into the joint through the longitudinally split patella. In it the rectus muscle, patella, and ligamentum patellae are split in the axis of the limb, no fiber being divided, thus having advantage over all other methods of opening the knee. It gives excellent access to all parts of the joint, even the posterior parts can be explored by sight, when the knee is flexed; and it does away with the need of that "septiciferous" process, putting a finger into the joint. To use fingers at the operating-table is usually as bad manners as to use them at the dinner-table—a very

The conclusion of the operation is simple and quick. The synovial membrane above the patella is closed by a fine continuous catgut suture. This is important as it prevents blood from the loose areolar tissue above the subcrureus pouch from entering the joint. The split in the rectus muscle and ligamentum patellae is closed by another continuous catgut suture, which also holds the two halves of the longitudinally split patella together and holds it so efficiently that a roentgenogram taken a day or two after the operation shows "no injury to the patella obvious." Sides of the wound are approximated by three or four rectangular (mattress) sutures of catgut, and the edges coapted by a continuous suture of fine catgut with the stitches close to the skin and to one another. These stitches need never be removed. No splint is necessary but its use for twenty-four hours is beneficial. After that a nervous patient can have the limb bandaged in wood-wool. The wood-wool can be removed from time to time and the patient allowed to move the leg. I never hurry convalescence, the patient remaining in bed about three weeks. Massage and electrical stimulation of the muscles can be begun a few days after operation. Passive movements are hardly ever necessary. Active movements by the patient are much better, and even a nervous patient may be encouraged to make them.

A study of the physical geography of the knee will give some clues to the parts played by the various component structures in the physiology and pathology of the joint. At the knee a convex bone (the femur) is held to a flat bone (the tibia) by a capsule of fibrous tissue, thickened at the lines of stress at the sides into ligaments, the external and internal lateral ligaments. But if this was all, the length of the capsular ligaments would allow the tibia to move in all directions on the femur, as well as backward and forward. Such a joint would be horribly unstable and unsafe. To remedy this there are placed inside the knee-joint two sets of structures, the crucial ligaments and the semilunar cartilages. These are united in part at their tibial attachments, both in front and behind. Together they give strength and firmness to the joint, limiting the gliding of the femur on the tibia. In the normal movements of a joint they will sustain no harm, but should the movements become exaggerated, as in a wrench or sprain, they will be damaged. Naturally also the structure which bears most strain in ordinary life will be most liable to sustain damage in extraordinary movements. It will also be the strongest and therefore the best able to withstand a shock. The crucial ligaments are the strongest ligaments in the knee-joint and bear by far the greater part of the strain. In an accident, as in ordinary life, the severest strain will fall on them. Hence it is to be anticipated that injuries to them will be both frequent and important. We know little

Fig. 5.—The crucial ligaments in a flexed knee, anterior view.

Fig. 4.—A method of closure of the wound in median arthrotomy. A, the synovial membrane closed by two (one suprapatellar and one infrapatellar) continuous catgut suture. important point, for unless certain of his aseptic technique no surgeon has the right to recommend a patient to allow him to open his knee-joint. This operation was advocated recently in the first number of the *British Journal of Surgery* by Mr. Robert Jones of Liverpool for access to some results of injuries to the spine of the tibia. He has now extended its application with satisfaction and success.

such injuries, probably because they would not be fatal, and the deep situation of the ligaments renders their inspection difficult. There are clinical signs, however, which would indicate their lesion.

1. Movement of the tibia on the femur.
2. Any dropping back of the tibia of the femur.
3. Any rotation of the tibia on the femur, almost always external.

In all these three signs the leg must be carefully compared with that of the other side, which should not previously have sustained an injury. In an old knee injury none of the above-mentioned signs need be found so that a most valuable symptom is the patient complaining of lack of stability in the joint, the knee giving way, the patient feeling afraid to trust to it. Such knees are well known clinically as "slipping knees," and are, I believe, produced by the sliding of the femur on the tibia. If a group of patients in whom the result of the operation for the removal of the semilunar cartilage is unsatisfactory are examined, a very large number will be found to have slipping knees. Normally a little rotation of the tibia on the femur is permitted. But this should be the same on both sides and can be easily seen if the patient sits

Fig. 6.—The crucial ligaments in a sagittal section of the knee; A, flexed, B, extended. This is taken from a standard text-book of anatomy and is designed to show the anterior crucial ligament tight in extension (B) and the posterior crucial ligament tight in flexion (A). This is wrong; both are taut in full flexion and full extension and both are slack in semiflexion.

down with legs extended and heels on the ground. Look to the position of the feet. This rotation is not limited by the crucial ligaments only, but also by the semilunar cartilages. Two general remarks may be made.

1. The *crucial ligaments* bear considerable strain in all movements of the knee and seem most prone to injury in exaggerations of flexion and extension of the knee, that is, by movements in a vertical plane, the patient standing. With lateral movements an injury of the lateral ligament, almost invariably the internal lateral, must sustain damage, partial rupture, before the crucials are dangerously stretched.¹ Rotation movements of flexed knees are more likely to produce injuries to the semilunar cartilage, which injuries are made permanent or increased by subsequent movements of extension. For instance, by it the displaced cartilage may be fractured.

¹ Corner, Edred M.: The Role of the Crucial Ligaments in the Knee-joint and Injuries to the Knee, *Lancet*, London, May 9, 1914, p. 4,007.

2. The *semilunar cartilages* bear most strain and are most likely to be injured with movements of rotation with semiflexed joints.

Other ligaments of the knee are not likely to be injured with the exception of the internal lateral ligament, whose injury I believe to be a preface to, when partial, that of the crucial ligaments; and when complete, a sequel to the complete rupture of the crucial ligaments.

Before we leave this subject it will be well to recall to mind that when the crucial ligaments bear a strain their bony attachments bear that strain also. Partial rupture of these ligaments is often overlooked. I must confess that I have encountered one instance which I believe to be due to the bony union of an overlooked and partially detached spine of the tibia. So far as our knowledge goes at present, the anterior attachment of the anterior crucial ligament is most often detached alone. The other three attachments of these ligaments often seem to escape. Such ideas must be received with great caution, however, as the tibial attachment of the anterior crucial ligament is the one which is more easily seen than the others and naturally we come to knowledge of it first. It is said

that with rupture of the anterior crucial ligament there is pain and disability on extension of the limb; while with a lesion of the posterior crucial ligament there is pain and disability on flexion of the knee. I do not think that it is possible, clinically, to dissociate tension on these two structures. With injury to these liga-

Fig. 7. — Semidiagrammatic sketch to illustrate the skin-line with and without partial rupture or stretching of the crucial ligaments produced by the external rotation of the tibia of the femur, right leg.

Fig. 8.—Showing the strain placed on the crucial ligaments in movements of the knee-joint.

ments there is pain both on full flexion as well as on full extension of the joint. In fact, there is pain on all extremes of movements of the knee, flexion extension or rotation, because the crucial ligaments are tightened by all these movements; hence their liability to injury.

The strain on the crucial ligaments is not all. The synovial membrane is loosely attached round the front of the knee, where it must move with movements of

the joint, but is closely attached to it as it covers the crucial ligaments and the back of the joint where there is no need for it to move. Stresses and strains in that situation easily tear it even if there is nothing but a slight and temporary stretching of the crucial ligaments. The roentgenograms of the artificial (wire) anterior crucial ligament show that the loops separate with flexion and extension of the joint,⁴ thus giving

Fig. 9.—The roentgenogram of both knees is shown so that the external tubercles of the tibia may be compared as they exist in each knee. That on the left side is much sharper and more slender; possibly it was broken and partly detached by the accident, uniting with extension of ossification into the anterior crucial ligament.

some idea of the amount of stretching which the crucial ligaments are constantly undergoing. Bleeding thus caused will lead to the joint becoming filled with blood and, later, synovia, a condition of hemarthrus. Formerly it was never quite understood why blows on the knee should give rise to synovitis, the joint becoming full of bloody fluid. Now it is intelligible. The force of the blow is transmitted, say, from the patella to the femur, which it attempts to drive backward, but is prevented from doing so, in part, by the crucial ligaments. These ligaments, particularly the anterior one, are stretched, and the tightly bound-down synovial membrane over them is torn. Hence hemarthrus and traumatic synovitis. The blood comes from some small intra-articular lesion caused by some slight displacement of the femur on the tibia, or *vice versa*; and the effused blood acts as an irritant to the synovial membrane, inducing inflammation and hypersecretion. From this we may learn that the sooner the effusion of blood ceases and the effused blood is removed from the joint, the better for the patient. Mere tapping cannot do this. The joint should be opened and washed clear. The tear in the synovial membrane, or otherwise, can be sutured or not according to the case. I would commend to your notice the possibility of taking this unusual step in what seem to be "bad" cases, and for this reason. The synovial tear, or tears, will heal by a layer of fibrin being deposited on it, like healing under a blood clot or scab. If this fibrin becomes displaced by a movement of the joint

another layer of fibrin will form. The displaced fibrin may be removed by the leukocytes, or it may be shed into the joint. If it does the latter, it may form the nucleus of a loose body in the joint. I would suggest that in many cases the signs of the inflammatory origin of a "joint-mouse" are secondary to the repair of some trauma.

On looking through the records of sixty-one cases in which loose bodies were removed from the knee-joint and recorded in the St. Thomas' Hospital Surgical Reports, one cannot avoid being struck by six things:

1. How uncommonly the origin of these loose bodies is ascertained.
2. How often they are multiple.
3. How often they are called recurrent.
4. How often they consist of fibrin.
5. How often they are temporarily lost in the joint.
6. Apparently how long they can be present without causing any urgent symptoms.

The detached fibrinous plaque grows like a crystal in a saturated solution of its own salt. It becomes triturated and rolled by the movements of the joint and it would appear that at times it undergoes bony or cartilaginous changes. I have found bodies, previously felt loose in a joint, attached to the synovial membrane. For a loose body to become so attached is a distinct reversal of the generally accepted idea that nodules in the synovial membrane may become detached and form loose bodies.

I would suggest that the majority of loose bodies in the knee-joint have an origin in a tear in the synovial membrane of the posterior part of the knee-joint, particularly in the thin and tightly bound-down synovial membrane over the crucial ligaments. Such an idea suggests that a free exploration of the knee-joint be done more often in cases of hemarthrus. This is

Fig. 10.—Anterior-posterior roentgenogram of a knee in a case of ruptured anterior crucial ligament in which a new anterior crucial ligament was made with two loops of silver wire. The patient was shown to the Clinical Section of the Royal Society of Medicine, London.

Fig. 11.—Lateral view of the knee shown in Figure 10.

alone justifiable with modern technic. The knee-joint is not more prone to grow foreign bodies than other living tissues. Yet such bodies are rare in other joints! Can it be so because they have no such arrangements as there are about the crucial ligaments of the knee?

4. Corner, Edred M., and de Mowbray, R. M.: Fractured Spine of the Tibia, *Proc. Roy. Soc. Med., Clin. Sec.*, April, 1914, p. 122.

To the question when to open a joint after an injury the answer is either at once or as soon as the hemorrhage has ceased. To do all this satisfactorily I would urge the use of the method of opening the joint by splitting the patella longitudinally. The method reveals a further series of problems, commencing with the question of tapping the joint.

When the patella is split longitudinally, it is seen that the knee-joint consists of three cavities, two simple and one complex. The first cavity, the suprapatellar, lies on the femur, above the patella, whose contact with the femur very largely divides it off from the middle chamber of the joint. The middle chamber is formed by the patella above and by the ligamentum mucosum with its alar ligaments below forming a diaphragm across the joint by extending from the front of the joint to the condyles of the femur behind. The third or posterior chamber lies behind this diaphragm, between it and the posterior ligament of the knee-joint. It is complex, as the crucial ligaments project into it from the posterior wall, like a partition which does not reach the anterior wall and imperfectly divides the chamber into two lateral halves, communicating in front.

Fig. 12.—Sagittal section of knee, showing the three main chambers in it: suprapatellar, middle, and posterior.

When the knee is distended all three chambers communicate with each other. The patella is raised from the femur by the fluid distending the joint, throwing the upper and middle chambers of the joint into wide communication. The progress of the communication is directly proportional to the tension in the joint; but as the joint is tapped and the distention lessened these cavities cease to communicate so freely. It is quite impossible to empty the knee-joint by tapping. The suprapatellar and the middle chamber can be emptied but not the posterior. It is in the nooks and crannies of the complex third and posterior chamber that the organisms of infection will find most peace and quiet to enable them to multiply and grow strong. This is the most important chamber to empty and at the same time the most impossible. Who wonders that treatment by the tapping of the knee-joint is ineffective? It is like removing the smoke but allowing the fire to burn. Almost its only use is to supply a specimen of fluid for examination.⁵

Let us apply this knowledge to the lavage of a septic joint. For success it is desirable, if not absolutely necessary, to wash out thoroughly the posterior chamber of the joint. This cannot be done while the ligamentum mucosum and the alar ligaments are intact, so they must be cut away or the femoral attachment of the ligamentum mucosum separated, then carefully all the nooks and crannies of the complex posterior chamber of the joint washed out, this being done, if at all possible, without cutting away the ligamenta alaria, because of the oozing of blood which may take place afterward. For similar reasons the synovial membrane above the patella should be closed with continuous catgut suture. It prevents blood from the loose tissue between the crureus muscle and the

suprapatellar pouch of synovial membrane entering the joint cavity. The surgeon should avoid, if possible, splitting the synovial membrane over the pads of fat below the patella. If he does split them, the edges must be sutured. I suture the rectus muscle above the patella with another suture, which is continued over the patella to join the halves of that bone and of the ligamentum patellae (Fig. 4). The bone requires nothing more. Wiring is not needed. Yet in the great majority of cases a roentgenogram taken shortly after operation shows no obvious injury to the patella. The skin is closed by a method devised to insure the complete and rapid closure of the wound. The sides of the wound are approximated with two, three, or four mattress sutures of catgut. These edges are then coapted by a continuous suture of catgut, the stitches being inserted close to the skin edge and to each other, securing the almost immediate sealing of the wound. Movements may be commenced at once; and after twenty-four (or twelve) hours all dressings can be discarded.

I have experimented with many catguts. Those whose sterility is acquired with chemicals, for instance, chromic acid, mercuric chlorid, etc., are unsuitable. As the catgut is absorbed minute doses of these chemical irritants are set free in the wound, yielding in many cases a moist, almost eczematous, condition of the superficial wound. Iodin catgut is better, but the gut can be so hardened by iodine as to be almost unabsorbable. The wounds, however, are drier. In fact, plain iodized catgut sterilized by heating in some non-irritant fluid, for instance, xylene (xylol), seems to be best suited for this purpose. The stitches need never be removed. Suture without drainage is best; but the

Fig. 13.—Leg fourteen days after operation, extended.

Fig. 14.—Leg fourteen days after operation, flexed.

wound, not the joint, can be drained in the upper part of the wound by a tube inserted into the areolar tissue between the quadriceps muscle and the joint. If drainage should become necessary later it can be done in the popliteal space and always a few days after operation.

In all cases with pyrexia the popliteal space should be examined at every dressing and compared, for fulness, with the popliteal space of the other leg. Pus escapes easily from the posterior chamber of the knee-

5. Corner, Edred M.: *Clinical Lecture on the Treatment of Joint Disease*. Med. Press and Circular, May 13, 1914, p. 484.

joint along the azygos vein into the popliteal space. In the popliteal space it is shut in by the dense, tough popliteal fascia which forms a roof over it, causing it to travel by the way of least resistance up the thigh under the hamstring muscles and down the leg under the gastrocnemius. The overlooking of the escape of pus or any infective material from the knee-joint into the popliteal space is very easy and its results, owing to its deep extensions, are very disastrous, often leading to the loss of the limb or to pyemia. I would strongly urge that it is better to make even an unnecessary incision in the popliteal space than run the risk of overlooking this escape.

TREATMENT

1. *Stretched or loose crucial ligaments.* This is almost invariably the anterior. With a drill a hole is driven through the external condyle and through the loose ligament. On it an unabsorbable suture is threaded and one end drawn through the condyle. The other end is passed once around the ligament and the end withdrawn, *secundum artem*, through another hole made through the external condyle, not far from the first. By tightening this suture the corresponding crucial ligament is tightened or reefed. A similar maneuver would tighten a loose posterior crucial ligament, but I have never found it necessary to do so. That ligament seems almost invariably to escape and it would seem that the anterior crucial ligament is stretched and ruptured before the posterior can be hurt.

I do not believe that there can ever be a stretching or rupture of the posterior ligament unless the anterior yields first.

By tying the suture the ligament is reefed and made tighter. The suture is tied with the knee a little flexed, as when the ligament is tightened in this position, the joint will be extended subsequently but little beyond it. Patients all admit that this strengthens their knee. The holes are drilled through the external condyle to tighten, or reef, the anterior crucial ligament; because that ligament is attached to that condyle. The posterior crucial ligament would be "reefed" through the internal condyle.

2. *The semilunar cartilages.* When a knee-joint is injured many structures within it may be affected, and from time to time it becomes necessary or advisable to remove a semilunar cartilage. The figures for St. Thomas' Hospital, London, show that it is sixteen times more frequent to operate on the internal cartilage than on the external. The operation of removal of the cartilage can best be done through a comparatively small incision on the corresponding side of the joint. Clinically one is sure that if the cartilage suffered sufficient damage to fracture or dislocate it, other structures in the joint will also have been injured. If the injuries to these structures cannot be put right, the result of the operation on the cartilage will be unsatisfactory. I would urge that, in certain cases, the asymmetrical local incision for removal of the cartilage be not made, but a median one, such as that of splitting the patella longitudinally, be made so that everything in the joint can be examined. Particularly is this so where the clinical diagnosis is vague, such as "internal derangement of the knee." By this method there is very excellent demonstration of the joint and I have found wonderful and undiagnosed fractures and dislocations of the cartilage, intra-articular fractures of the femur, "foreign" bodies, injuries

to the crucial ligaments, fractures of the spine of the tibia, and so on. If the work is done thoroughly there is less danger of doing it without satisfaction to the surgeon or patient.

3. *Internal derangement of the knee.* When the knee is injured the resultant traumatism falls on many structures, not on one. It is more or less comparable to internal derangement of the abdominal viscera, enteroptosis. It is therefore necessary to open the joint thoroughly and see what is the matter and take steps to correct it. The faults in a knee-joint may be many: injury or dislocation of the semilunar cartilages, injuries to the crucial or other ligaments, intra-articular fractures of the femur, fractures of the tubercles of the spine of the tibia, and, if the case has gone on long, hypertrophied fringes of the synovial membrane, or loose bodies may be present. One must not be satisfied with finding one fault, many may need to be corrected. From the point of view of prognosis, diagnosis and treatment, the median and general incision is to be recommended, as it allows of a wider and more exact line of conduct.

There is one point especially to which I would like to refer. Certain patients feel that the knee is not strong, is not to be trusted, gives way unaccountably. In these patients at operation it is found that the anterior crucial ligament is "slack," having been injured, stretched, or partially torn, and that an elevator is easily thrust between the internal condyle of the femur and the tibia. The condyle, by slipping on the tibia, gives the patient the feeling of insecurity and untrustworthiness in the knee and accounts for the knee giving way and the patient falling. Let that crucial ligament be rendered taut, or reefed, and the knee will be much strengthened. In fact, the surgeon may feel sure that at the operation the ligament will be "overreefed" and the patient slow in recovering full movements of the joint because of the overtight ligament. This merely necessitates a longer convalescence but with as good result. I would say that it is better to overreef than underreef the ligament. By overreefing the surgeon has something in hand which he can afford to let go—his patient is above the line of security; an underreefer has not, and his patient is below the line of security.

Of recent years, since it has been proved that the operation can be done safely, it has unfortunately become the custom to remove internal cartilages from the knee-joint with comparatively little thought. Indeed, one feels that at times the cartilage is removed with even less consideration than the appendix. The patient is almost always better temporarily, owing to the postoperative stiffness and apparent strength of the knee. The existence of such a state of affairs is perfectly natural in the evolution of surgery; but it is no great credit and the sooner it is modified by some method enabling the surgeon to take a wider and more general view of injuries to the knee, the better. To how many doctors is injury to the knee synonymous with injury to the semilunar cartilage?

4. *Intra-articular fractures of femur.* They consist of fragments broken off, usually from the internal condyle. This part of the femur is much more liable to injury than the external condyle. Hitherto the practice has been to remove the fragment, and I have followed it, but I believe that the proper treatment is to replace the fragment and maintain it in position by a rectangular catgut stitch passed through the condyle of the femur. I cannot think that depriving the

articular surface of the condyle of a square inch or more of cartilage can be beneficial to the joint. Indeed, I believe it to be a common cause of chronic synovitis after injury to the joint.

It is noteworthy that both the internal condyle and the internal semilunar cartilage are much more often injured than are the corresponding parts of the other side. The explanation is found in the more extensive movement of the internal condyle of the femur on the tibia, the greater amplitude of movement offering more chances of injury. Rupture, complete or partial, of the crucial ligaments, particularly the anterior, would result from the superlative exaggeration of such rotation of the knee. It can be easily understood that such an extensive and violent rotation is hardly possible. So any injury to the posterior crucial ligament is very rare.

5. *Fractures of the spine of the tibia.* The subject of fractures of the spine of the tibia and rupture of the crucial ligaments of the knee has been reviewed and made the subject of a masterly paper, such as we should expect, by Robert Jones of Liverpool and Alwynne Smith of Winnipeg, in the first number of the *British Journal of Surgery*, July, 1913. In it they record seventeen cases which they have seen in the last three years—a truly large number, which tells that we humbler mortals fail to recognize the true nature of the cases we see. They urge that these cases should be treated conservatively. Perhaps this is the mature wisdom of more years than those of which I can boast; but I never like to leave blood in a joint, and a loop of catgut to form a rectangular intra-osseous suture in the tibia to anchor the detached spine would seem to me to be more in keeping with the surgical practice of to-day than the removal of the detached bone: the convalescence would be shorter, and the functional results should be better.

Some authors speak of detachment of the ligamentum mucosum from the femur as an item in the internal derangement of the knee. I have had no clinical experience of it except as an incident in much more serious injuries. I would regard its presence as an indication that the joint had been severely injured and that other injuries were to be looked for, if not actually present.

ABSTRACT OF DISCUSSION

DR. JOHN B. MURPHY, Chicago: Mr. Corner's paper is certainly a distinct, positive statement of the line of procedure that should soon become a habit. We have been too fearful of opening joints. We have been too willing to accept the external physical evidence and later the Roentgen ray evidence as to the lesions in the joint. If I were to give a percentage I would say that between 40 and 50 per cent. of the later cases of knee-joint lesions which incapacitate the patients have no Roentgen ray or other signs sufficiently positive to justify a procedure from that evidence alone. That is why the line laid down by Mr. Corner is one that is going to be followed. The lateral is not nearly so good as the median incision. It took us a quarter of a century to learn the technic of conservative exploration of the peritoneum, not to touch the surfaces, except when there is an absolute necessity for it. One should not keep sponging and rubbing and handling the synovial membrane of a joint more than one would a peritoneal surface under the same circumstances. If it is done as much as with the peritoneal surface great effusion will follow the operation. Do all of the work with instruments without sponging, handling or manipulating the synovial membrane. That is the key to the work. The median division of the patella and its ligaments above and

below is no more serious than the division of the bone in any other position after one learns. I was particularly interested in the fractures of the spine of the tibia. Visitors to my clinic will recall that I had two patients of this type in which I had exostosis after the fracture so that it incapacitated the patient and had to be removed by the chisel through the joint. We are only beginning to appreciate the significance of recurring traumas in joints, as pinching of the capsule, fracture of the semilunar cartilages, intra-articular villous formations, etc. Recurrent mild internal traumas in joints are extremely injurious to the synovial membrane and induce hypertrophy, fibrosis, synovitis, etc.

DR. HENRY O. MARCY, Boston: Mr. Lister taught me when I was his first American pupil that it was not so serious a thing to open the knee-joint as had been earlier supposed. To open the knee-joint in the early days of surgery was considered entirely beyond the realm of correct operation. When in 1880 I reported 150 operations on the knee-joint I hesitated to read the paper. I expected only criticism and no approval. Dr. Rowe said "To-day we have learned a new chapter in operations on the knee-joint." Dr. Sayre said to me "You have made a devil of a row in my line of surgery to-day," and that was an expression of the possibilities of opening the knee-joint at that time. The operations on the crucial ligament are something quite new to me.

DR. FREDERICK J. FASSETT, Seattle, Wash.: In opening a knee-joint through sagittal section I have been impressed with the close attachment of the crucial ligament to the cartilages. Would the crucial ligament play a part in the loosening of the semilunar cartilage? Given a diagnosis of a loose semilunar cartilage, would this be the incision of choice?

MR. E. M. CORNER, London, England: Do the crucial ligaments play a part in the loosening of the internal semilunar cartilage? The answer is yes, they do play a very great part. If the crucial ligaments in bearing the strain give way, no further injury is likely to occur. If the crucial ligaments stand firm then the semilunar cartilages, particularly the internal, will probably yield. You will meet in practice a mean between these extremes; partially lacerated, stretched or torn crucial ligaments and in direct degree their slackness will the injury to the internal semilunar cartilage vary. The greater the slackness the less the likelihood of injury to the cartilages. The second question, concerning the median incision as the operation of choice removal of the semilunar cartilage—if the clinician is absolutely certain in his own mind of the diagnosis of a located semilunar cartilage, then he will do better to open through the small local incision. The patient will get better sooner. If, on the other hand, the surgeon is not so certain or the knee-joint is not well after he has removed the internal semilunar cartilage, it is wise for him to decide on exploration of the knee-joint through the larger median incision. With regard to satisfaction after operation for semilunar cartilage, I would like to add a word of warning, namely operation on the knee-joint gives a certain amount of operative stiffness and limitation of movement which it takes weeks or months to pass off. This postoperative stiffness gives to the patient an impression of strength in the joint. Shortly after operation patients will tell you that they have a stronger knee. If you see these people, say a year or half after operation, some of them will tell you quite a different tale. So that in deciding whether a case is satisfactory or unsatisfactory it is well to wait at least a year before making that decision.

The Individual Responsible.—That which is a common concern to all is very generally neglected. The energy which is stimulated by that which depends on himself, of which he only is to reap the whole profit or which concerns common to him with others he employs as much attention and activity as his neighbor requires. He neglects that of which he thinks others take care, and as other men prove equally negligent, his own interest is universally abandoned.—Aristotle

In experiments on the intact animal under ether or chloretone anesthesia I found that the injection of sodium tartrate in various concentrations, from 2.5 to 10 per cent. and 20 per cent., the force of the heart was considerably decreased. The frequency was slightly diminished or remained unchanged. One c.c. per kilo of a 10 per cent. solution caused a marked decrease of amplitude. But in some experiments smaller doses produced the same effect. In one dog

pressure was moderately increased in most instances when ether anesthesia with morphin or curare was employed. No effect with tartrate on blood-pressure was observed when chloretone was employed as an anesthetic. Oncometric measurements of the kidney have invariably shown considerable increase in volume. Attention may also be called in this connection to some observations with calcium chlorid. The antagonistic action of calcium and the oxalate has been shown by a number of investigators. Some workers explained the action of the citrates and tartrates by the chemical property of these substances to form calcium compounds that are insoluble or are not dissociated. Experiments with a calcium chlorid solution have shown that it is antagonistic to sodium tartrate, as it counteracts the effect on the heart as well as on blood-pressure.

The effect of sodium tartrate on the isolated heart has been studied by Karczag,⁶ who made experiments on the heart of the turtle. He reported that hundredth-normal tartaric acid in Ringer solution produced heart-block and decreased cardiac action. Gros⁷ recently reported experiments showing that tartrates also produce depression of the frog heart. I have carried out a systematic study on the isolated heart of the dog, cat and frog. Sodium tartrate, even in very dilute concentration, was found to be a cardiac depressant. A solution of three-hundredth-normal perfused through the frog's heart for from thirty to sixty seconds produced a distinct though not a very pronounced diminution in amplitude. With the increase of the concentration there was greater decrease in the action of the heart which was not, however, proportional. A solution of hundredth-normal decreased the amplitude 40 per cent. After perfusion for the same length of time with a tenth-normal solution the effect was a little more than twice as great. The action varied also with the length of time perfused, cardiac depression being more marked when larger intervals were employed. No adequate explanation of the action of sodium tartrate can be offered at present. Although our experiments show very decidedly the antagonistic effect of calcium under certain conditions, it utterly fails to account in some cases for the action of sodium tartrate.

I am very much indebted to Mr. Selig Hecht, Graduate Scholar, Harvard University, for valuable assistance in some of the experiments of this investigation.

The Limitations of Statistics.—A series of hundreds of operations, tabulated and arranged and nicely rounded off in terms of percentages, always seems to me to possess but very limited value, so limited, indeed, that it is strictly confined to one person—the surgeon who performed the operations; and even he can learn nothing from the contemplation of his tables when he has compiled them. The rich experience he will have gained cannot even be expressed in that way; much less can it be imparted to others, for it will consist actually in the sum of a multitude of observations of individual cases, all of them slightly varying one from another, but all of them obeying pathological laws which are fixed, and which never vary. After all, it is not the fact of performing a large number of operations that in itself constitutes real experience, unless in addition the surgeon who performs them possesses the qualities that are essential for a good clinical observer.—R. Hamilton Russell, *British Medical Journal*.

Fig. 3.—Upper tracing shows the depressing effect of sodium tartrate on the heart, the record being taken by means of a Cushny myocardiograph, with the heart *in situ*. Lower tracing shows the antagonistic action of calcium chlorid and sodium tartrate when injected intravenously. Dog under chloretone anesthesia.

weighing 9 kilos, the intravenous injection of 15 c.c. of a 2.5 per cent. solution of sodium tartrate under chloretone anesthesia produced a decrease of 25 per cent. in the amplitude of the heart as measured by a Cushny myocardiograph. Recovery was the rule in our experiments. The rate of injection had an appreciable effect. The more rapidly the solution was introduced the more marked was the depression. Blood-

STUDIES IN INTESTINAL OBSTRUCTION

WITH A REPORT OF FEEDING HETEROLOGOUS
JEJUNAL AND ILEAC CELLS TO A
HUMAN BEING*JOHN WILLIAM DRAPER, M.D.
NEW YORK

To Roger we are indebted for the present conception of the cause of death in intestinal obstruction. He was undoubtedly the first to conceive of it as a true auto-intoxication.

In a paper read before the Johns Hopkins Medical Society seven years ago and based on a study of the effects of 400 duodenal obstructions produced in animals at the Surgical Research Laboratory at Columbia, I reported corroborative evidence, from a surgical aspect, of Roger's view. William Welch on opening the discussion of my paper said that, if corroborated, the facts presented would show that the duodenum had a function hitherto unknown and one evidently of the utmost importance in medicine. It is gratifying that this corroboration has just recently come from Dr. Welch's own laboratory at the hands of Whipple and his associates. By a series of skillfully devised experiments, these investigators have succeeded in casting much more light on this interesting problem than either Roger or I had been able to do, and the sum of our investigations taken in the aggregate seems now to offer incontrovertible proof that the cause of death is not bacterial in origin, but truly autotoxic from the cells of the epithelium of the intestine itself.

Perhaps no branch of medical research better illustrates than this one the advantages derived from having men with one object in view working at different centers of education toward the solution of a common problem. The different points of view ultimately arrange themselves on convergent lines so that when the answer is finally won it is evidently not the product of one man's aims or ambitions, but a homogeneous unit, resulting from the constructive work of several minds. For no single individual can expect to do much more with a modern problem than to advance it a single step. This problem also serves to demonstrate the rapid breaking down of the traditional barriers between medicine and surgery, forecasting the ultimate fusion of these old and arbitrary subdivisions into a new unit, the members of which will have a working knowledge of physiologic chemistry and its allied sciences in addition to requisite technical skill. Furthermore, it demonstrates that modern surgery, like physiology, does not consist in the manufacture and use of instruments of mechanical precision but in philosophical interpretation of natural phenomena.

The various old and groundless theories as to the cause of death in intestinal obstruction have one by one been disposed of, with the possible exception of the exact origin of the toxemia. Is it bacterial, or

purely autotoxic from the cells of the intestinal epithelium itself? Were it not for the views of F. Murphy, which result from his studies at the Washington University and which bear evidence favorable to the bacterial theory, one would be ready to accept the result of the painstaking and thorough researches at the Cornell laboratories of Hartwell and Hoguet who seem definitely to have excluded the anaerobes, and of Whipple and his associates at the Hopkins laboratories, who are disposed to rule out all bacteria as causative agents in the development of the toxemia. From the prosaic and common sense point of view of applied surgery, it is hard to understand why obstruction in the duodenal region should be many times as dangerous as obstruction in the colon. It has long been known that duodenal contents may be allowed to escape into the peritoneal cavity without danger, but that peritonitis is to be expected if any colonic contents escape.

No careful observer could watch the death of a series of duodenally obstructed dogs without noticing the close similarity between the ante-mortem symptoms of this condition and those seen after parathyroidectomy or long remain in doubt that the function of the liver was greatly impaired in each.

The accompanying tables are based on the study of the urine of duodenally obstructed dogs, both

Fig. 1—Above, the split colon of a normal dog; in the middle, the split colon of a dog salivated for four days by pilocarpin, and below the split colon of a dog dying from acute duodenal obstruction.

before and after a large dose of camphor had been given hypodermatically. The recovery of the paired glycuronic camphor has been made by the method devised by Tollens. I am indebted to Frederick W. Schlutz of the University of Minnesota for the privilege of presenting these results, which are a chronicle of his chemical studies made on dogs obstructed by me. In a previous communication we have jointly presented two similar studies, both of which appear to show more conclusively than the present ones that liver function was impaired. Negative findings, reported of carefully wrought work, are, however, just as valuable as positive findings, particularly in the case of a method which is as yet open to some question as to accuracy, and which is certainly open to criticism as regards the time taken in working it out. Dr. Schlutz is carrying on further studies of the accuracy of Tollens' method. As indicated in Table 1, the discrepancy between this report and our previous findings, in which the liver function, as indicated in terms of camphor-glycuronic was considerably lowered, may be due either to inaccuracies in the method itself or our application of it, or to the fact that we were unfortunate in having one of our live but a very short time while the other one an unusually long time. Dr. Schlutz will

ther report which will clarify this interesting question.

When Hartwell and Hoguet advanced their hypothesis that water privation was the chief lethal factor after intestinal obstruction, at the suggestion and with the help of George Wallace we conducted some experiments to determine the exact water percentages in the tissue of dogs under various conditions. It was thought that salivation by pilocarpin, fasting, and duodenal obstruction might cause approximately the same water-loss to the tissues. Table 3 shows the results from six tissues, namely, liver, lung, heart, kidney, spleen and muscle. It is seen that within a few tenths of 1 per cent. the water-loss after pilocarpin, after fasting, and after death from duodenal obstruction was the same, namely, 10 per cent. In the case of the salivated dogs and the fasting dogs, euthanasia was practiced on the fourth and seventh day, respectively, long before there were any signs of disability. On the other hand, the duodenally obstructed dogs were allowed to die of their autotoxemia, so Table 3 gives the maximum water-loss for obstruction but not for salivation or for fasting.

Fig. 2.—Acute jejunal obstruction in dog. Stone swallowed six months before operation, causing chronic stomach symptoms, but no obstruction until it slipped into the bowel. Note partial digestion of soft area by gastric juice. Recovery followed removal of pebble and feeding of dog with jejunal and ileac epithelium.

These studies appear to offer additional proof that in intestinal-obstruction toxemia, as in other toxemias, whether bacterial or truly autotoxic in origin, the solvent power of water on the toxins and its help in eliminating them from the body serve in many cases to prolong life, and, under certain conditions, to save it. Indeed, Wallace has shown that an animal may be given double the lethal dose of diphtheria toxin and yet live, if treated by abundant hypodermoclysis. But while valuable from a therapeutic point of view they cast no light whatever on the origin or the nature of the toxins. Furthermore, it has been the clinical experience of all surgeons that even an abundance of water will not serve to save the life of a human being in whom there had existed for any length of time complete duodenal obstruction.

We have again subjected to careful microscopic study the liver, heart and kidneys of a large number of obstructed animals and find that except for capillary dilatation they appear normal. In this connection as well as in the conduction of the feeding experi-

ments, I acknowledge the efficient help of Dr. Eisberg. These microscopic findings are simply corroborative of previous reports made by myself and others. The beginning and end of the alimentary canal, however, on its epithelial surface, shows this capillary dilatation so markedly as to attract the eye on gross examination. I have shown a colored photograph of a stomach removed from a duodenally obstructed dog at the Mayo Clinic. I have shown and called attention to this before, without knowing its importance or significance; and because of its bearing on certain data which I shall present later, I am glad to say that the observation is corroborated by Whipple. In our necropsy experience the small intestine has shown little if any, gross change, but the colon is almost invariably affected and in a very characteristic manner. I understand from Wallace that the same condition obtained after a lethal dose of diphtheria toxin had been given.

Discrepancy with results previously reported may be due to short post-operative life or to inaccuracy of Tollens' method.

Thus it appears increasingly probable that the toxins of intestinal obstruction are eliminated both from the stomach and from the colon. When we recall the method of elimination by the stomach of morphin, its reabsorption by that organ and the value of frequent stomach-washings in the treatment of morphin poisoning, the post-mortem picture of intestinal obstruction is not so surprising, and the value of lavage and epithelial cell feeding in complete and incomplete obstruction as well as in acute dilatation of the stomach is more easily understood. It strongly suggests that most cases of postoperative dilatation are due to an adynamic duodenum, just as hydro-nephrotic dilatation of the kidney is often caused by physiologic ureteric obstruction. An organ dilates first at the point of obstruction to its outlet, be it obstruction mechanical or physiologic.

The capillary evidence of stomach elimination affords a working hypothesis on which we may

explain the interesting results of feeding to duodenally obstructed animals the epithelial cells from the ileum and jejunum of other animals. Table 4 shows the result, as regards the length of life, to be quite definite, the fed dogs living nearly twice as long as the controls. This series agrees with a similar series reported by me from the Mayo Clinic. It is not to

Postoperative life unusually long may indicate high liver resistance or inaccuracy in Tollens' method.

be forgotten that scrapings from the frog's duodenum will stimulate pancreatic secretion in the higher vertebrates. Intercellular reactions must be among the most ancient and most fixed of our functions, and the feeding of intestinal cells may prolong life by reestablishing certain vital intercellular reactions which the obstruction had interrupted. Although

knowing empirically that if jejunal and ileac epithelium were placed in the stomach of a duodenally obstructed dog, that dog would outlive one either not fed on cells at all or fed on cells of organs other than the small intestine. I could not previously understand this but it now seems probable that since the toxins are undoubtedly thrown out into the stomach they are directly rendered harmless by the heterologous cells from the small bowel derived from a healthy animal and are thus prevented from reentering the body. This explains the immediate benefits derived in the treatment of acute dilatation of the stomach and since this condition is undoubtedly due to physiologic duodenal obstruction, it seems probable that the feedings of these epithelial cells may prove to be just as useful in the treatment of dilatation as in the postoperative treatment of obstruction.

The study of Table 4, constructed from the last series, shows that it differs from the former series in that the pulse-rate of the different groups has been unaltered. A reasonable explanation of this is that the pulse was taken in the recent series at the femoral, whereas in the series reported from Rochester it was in each case taken at the apex. The femoral count is certain to be much lower when the heart is running high because many of the beats are not transmitted to the finger. While this series for the foregoing reason shows little change in the pulse-rate, it does show a much greater increase in the length of life, and this certainly is the best index of the effect of any treatment.

A glance at Table 4 shows that of the dogs fed with epithelium only two died before the hundredth hour, whereas of the controls only three lived beyond the hundredth hour. It is interesting to note that one of these lived 239 hours, showing that occasionally one finds an animal naturally resistant to duodenal obstruction. In the average this is balanced in the fed series by one which lived 284 hours, so that the general average remains unchanged and it is quite safe to say that the increase of life, which in this series is nearly doubled, is due entirely to the detoxicating effect of the epithelium.

In order to show that fed jejunal and ileac epithelium exercise some special detoxicating power not yet understood but definitely recognizable, we fed a control series of dogs on the emulsified cells of liver, spleen, pancreas and muscle-tissue. These animals lived a few hours longer than the not-fed controls, but it is evident that these cells had either no detoxicating action, or a very feeble one, compared with the intestinal epithelium. If we prove to have at hand

Salivation, fasting and duodenal obstruction each cause 10 per cent. water loss, showing this factor to be negligible in death by obstruction.

some less cumbersome method than Tollens' for determining liver function, it would be interesting to use it as an index of the effect of feeding small intestine epithelium.

I have utilized jejunal and ileac epithelium clinically in two instances. First in a valuable female dog which had been imported from England about six months before, and had had "chronic stomach trouble" ever since her arrival. She, however, whelped a large litter of pups about six weeks before I saw her, without difficulty. She was a large poodle, weighing about 40 pounds. She had had complete intestinal obstruction for five days and she presented all the clinical symptoms which I have described, notable tachycardia, extreme nervousness, and great weakness in the hind extremities. On opening her, with the consent and on the advice of Dr. Blair, I removed from the oral portion of the small intestine and at a point not exactly determined, the pebble which is shown in the illustration. Her condition was very grave, the pulse running from 180 up and showing great irregu-

were given until the entire epithelium from the two animals had been taken. The patient objected much more to some magnesia which we ordered, than to the dose of epithelium, which he described as "not half bad." The pulse improved and the patient lived. These cases prove nothing; they simply show that heterologous cells may be given without discomfort or harm.

Different operative procedures were used in each. In the first, the continuity of the bowel was reestablished and most of the pent-up products of obstruction were allowed to flow to the aboral portion of the intestine. In the second, owing to the patient's condition, it was found necessary to do an ileostomy, and all the obstruction products were drained to the surface. As I have already stated, it is by no means proved that because such products are toxic to other individuals, they are necessarily toxic to their host.

CONCLUSIONS

The power of the liver to pair camphor and glycuronic acid is probably seriously impaired after duodenal obstruction. This can be studied by the method of Tollens, which, however, is cumbersome and may be faulty. Such decreased power of camphor-pairing is presumably an evidence of impaired liver function. This, however, is not reflected in the histologic appearance, either grossly or microscopically.

The decrease in the water-content of the tissues in duodenal obstruction is about the same as obtains after salivation by pilocarpin for four days or after fasting for seven. As this decrease produced no visible change in either case before euthanasia, it is reasonable to believe that it produces none in intestinal obstruction. The loss is 10 per cent.

The toxemia in duodenal obstruction undoubtedly arises from an interference with cellular reactions of the intestinal epithelium. The toxins undoubtedly are at least in part eliminated from the stomach and colon. If small-intestine epithelial cells of healthy animals are placed in the stomach of duodenally obstructed animals, such animals have lived nearly twice as long as not-fed control animals. This evidence is strongly opposed to the bacterial theory of origin of the toxins.

In addition to the placing of jejunal and ileac epithelium in the stomach of postoperative obstruction cases, an emulsion of them should also probably be used in colonic irrigations for the same indication and purpose.

104 East Fortieth Street.

ABSTRACT OF DISCUSSION

DR. JOSEPH COLT BLOODGOOD, Baltimore: Dr. Draper's paper seven years ago made me think clinically about the duodenum in relation to some things we had observed in intestinal obstruction. In the beginning of surgery, we were dominated by anatomy, and then followed pathology. At present surgery does not look for much help to anatomy, except in certain regions, or even to pathology. We have about reached the limit of the microscope, but we do look for help to experimental physiology in the solving of problems which will be met on the operating-table. Perhaps, later, we will look to experimental chemistry. Surgeons, as soon as they conquered technic in surgery of the stomach, found that their patients did not die of peritonitis. As soon as they used anesthesia, the majority of their patients didn't die of shock and later of anemia, but up to the present there is one complication which has always bothered. If they do a posterior gastro-enterostomy a number of their patients vomit

larity at the apex. She was immediately put on small intestine epithelium derived from two dogs of a different breed. No one is justified in drawing any deductions from one case, but from a long experience with the symptoms of duodenally obstructed dogs, I should not under ordinary conditions have expected her to recover. The symptoms, however, gradually subsided and she lived.

The second instance in which I have used the epithelium therapeutically was in the case of a man referred to me by my colleague Jerome Lynch. The patient had had definite symptoms of obstruction for ten days, and when the abdomen was opened, an annular cancer was found which closed the terminal ileum. Not knowing whether heterologous epithelium would have any detoxicating effect, but remembering that the duodenal epithelium of frogs is capable of stimulating pancreatic secretion in the higher vertebrates, and realizing that this patient was in a desperate condition, Dr. Lynch and I decided to feed him the emulsion from a dog. Hourly doses

the contents of the duodenum, because of some fault in the technic. Now its contents are washed out with the stomach-tube. These patients in the beginning died because we didn't know how to use the stomach-tube. There was no place for the duodenal contents to flow. They couldn't pass up into the stomach and couldn't come through the anastomosis because it was kinked, and these patients died within from three to five days. When I heard Dr. Draper's paper I couldn't understand some of the mortality after operations of that kind, either of my own or others. Patients going well on the operating-table, apparently absolutely comfortable for twenty-four or thirty-six hours, suddenly going to pieces, with no pumping, no distension or rapid pulsing that show in intestinal obstruction. That is a definite case of death from acute dilatation of the duodenum as a definite postoperative complication. If there is a patent pylorus we can relieve that with a stomach-pump when the pylorus is closed by section. Some surgeons are now advocating that posterior gastro-enterostomy is without an element of danger, and will not be followed by complications in two or three days. The operation has led to chronic dilatation of the duodenum, a terminal condition which is responsible for the ill-health of a group of patients. In the last three years I have recognized and operated on six. In the previous three years I didn't recognize three. The previous three died. The subsequent six have recovered, and the cause of the dilatation I have found has been a congenital defect in the mesentery to the ileum from the appendix and the giant cecum descending into the pelvis, and on account of the short mesentery of the ileum lying directly on the base of the mesentery section, which kinks the small intestine as it passes through to a junction with the duodenum, which produces a chronic dilatation with its symptoms. These patients have been relieved by removing the colon and taking away that heavy part and exposing the transverse colon so that it will do its work and be allowed to expand. This is a demonstration of what experimental physiology can do for practical surgery.

ROVSING'S OPERATION FOR CONGENITAL CYSTIC KIDNEY*

F. B. LUND, M.D.

BOSTON

My first acquaintance with congenital cystic kidney was gained in the dissecting-room of the Boston City Hospital, where I saw several necropsies on patients of middle and adult life who had come into the hospital in convulsions and died of uremia. In some of them, the enlargement of the kidneys had been noticed before death; in others, not, but at the necropsy the kidneys were found very much enlarged and studded with numerous cysts ranging in size from a pea to an orange. These cysts were yellow, green, red and brown, and the effect was very beautiful, making a pathologic specimen truly remarkable and imposing in appearance. These necropsy cases were bilateral, one kidney being considerably more enlarged than the other.

Cases in which gradual enlargement of a polycystic character takes place in middle life, and in which the patients present themselves to the surgeon on account of dragging pain and the presence of a tumor in the loin, or possibly on account of the mobility of the enlarged kidney, may suggest malignant disease of the kidney or hydronephrosis; and it is frequently only when they are cut down on that their true nature is revealed and the importance of a knowledge of their

nature and treatment becomes evident. Such kidneys have not infrequently been removed, with the result that the patients have died of uremia, and the necropsy has revealed the presence of cystic disease of the other kidney, usually less advanced, so that a tumor was not felt before operation. A knowledge of the fact that this disease is usually bilateral might have saved the patient's life and the surgeon's discomfiture.

Congenital cystic kidney is a disease which frequently runs its course without a diagnosis being made during life, death occurring from uremia or cerebral hemorrhage due to kidney insufficiency. The real cause of the insufficiency is first discovered at the necropsy, when the enlarged cystic kidneys, not felt during life, are found by the pathologist. In fact, the course of the disease may be so latent that a patient in whom pathologic changes have not been suspected may be stricken with uremia or cerebral hemorrhage.

The term "congenital cystic kidney" does not include hydronephrosis, which is a dilatation primarily of the pelvis and sinus of the kidney from retention due to obstruction in the pelvis itself or the ureter, and does not concern the urinary tubules at all. It does not include cystic dilatation of the tubules due to contraction of the interstitial tissue, which sometimes accompanies a chronic interstitial nephritis. Here the kidney cortex becomes studded with little cysts, seldom larger than a pea, and not, as in the true congenital cystic kidney, greatly enlarged and varying in size. The cysts in interstitial nephritis play only a subordinate rôle and are secondary to scar contraction. Neither does the subject under discussion include the single or occasionally multiple cortical cysts which sometimes result from the absorption of embolic infarcts. In the true cystic kidney the organ may be enormously enlarged; for example, the cases in which they present an obstacle to parturition or in adults occupy half or two-thirds of the abdominal cavity. The whole organ, both cortex and medulla, is studded with cysts of various sizes, from that of a pin-head to that of a mandarin orange. The surface is knobby with cysts of different size and color. The walls of the cysts are thin and vascular, and the larger ones show folds on their inner surface, which are the remains of the walls of the smaller cysts which have coalesced to form them. The fluid consists of urine, since in it are found urinary constituents, such as uric acid and hippuric acid, calcic oxalate, cystin, leucin, and tyrosin; but in the larger cysts, this fluid is considerably diluted (probably by serum which has transuded through the walls), is albuminous, and contains blood, pigment, fat and cholesterin, in varying quantities, so that the color of the cysts may be red, brown or yellow, and the fluid in them more or less cloudy. Between the cysts are often found more or less extensive areas of normal renal parenchyma; other cysts are separated merely by fibrous tissue. In some cases with large amounts of parenchyma, we cannot distinguish between cortex and medulla.

The efferent passages, which protrude into the calices or pelvis frequently show no changes, but in some specimens are shrunk and narrowed, and may be almost obliterated. Thin-walled cysts may sometimes be seen projecting into the pelvis, just as they do on the outer surface of the kidney. Microscopically, each cyst is lined with a single layer of flat epithelial cells, which in the smaller cysts correspond closely to a tunica propria. In the larger cysts this is not found, either because they have no proper wall, or because

* Read before the Section on Surgery, General and Abdominal, at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

the cysts appear as dilatations in the interstitial tissue. The partitions between the cysts are so thin as to make it probable that the larger cysts have been formed by the coalescence of smaller ones. In some of the smaller cysts, glomeruli have been found attached to the walls, and flattened, but still permeable to injected fluid. It is thus evident that all portions of the tubular tract, from the glomeruli to the terminations in the papillae, are subject to cystic dilatation. The suggestion of certain investigators that these dilatations may arise by cystic degeneration of the interstitial tissue is not supported by recorded observations. That certain of the cysts show no epithelial lining is due to the fact that the epithelium is desquamated and disappears. In the smaller or younger cysts the epithelium is always found.

Cystic kidneys in adults and in the new-born are usually bilateral. If, as is rarely the case, the disease is unilateral, the other kidney is hypertrophied. The degeneration of the kidney may have an unfavorable influence on the development of the fetus, so that birth is premature. The child may die within a few moments of birth from respiratory failure, because of the interference with the movements of the diaphragm consequent on the tumor, or may live a few days, only to succumb to the same cause. Death may result early in these cases from renal insufficiency, the amount of normal functioning renal tissue between the cysts being insufficient for excretory purposes. On the other hand, the amount of normal renal tissue may be sufficient to prolong life for indefinite periods, perhaps decades, before renal insufficiency results in death. The most favorable conditions will naturally be presented by unilateral cases with compensatory hypertrophy of the opposite kidney, which unfortunately are rare.

In considering the etiology of this disease, we enter a field which has been fruitful of much discussion. The theory of Neuwerck, Hufschmidt and von Kahliden, that these tumors are cyst-adenomas, is negated, it seems to me, by the fact that the cysts may often be demonstrated to be dilatations of the renal tubules, and contain urine, often diluted with serum, it is true, but showing distinct urinary constituents. The epithelial proliferations and connective-tissue growths, which Brigidi and Severi had relied on as evidence of tumor-growth or adenoma, have been shown by von Mutach to be tissues characteristic of embryonic kidneys. The presence of these proliferations, etc., therefore, is an argument in favor of the developmental rather than the neoplastic origin of the tumors. In order to explain these cases we have to assume, with Orth and others, the existence of some obstruction to the escape of urine from the dilated and cystic canals. The oldest theory, that of Virchow, that the urinary concretions, "uric acid infarcts," so common in the new-born, have plugged the canals, is untenable, since these are rare during intra-uterine life, and after birth so common that cystic kidneys, if due to them, ought to be much more frequent than they are. There seems to be no doubt, as Virchow himself acknowledged later, that we must assume an organic obstruction and actual obliteration of the tubules. Orth agrees with Virchow's later view, that the condition results from a fetal inflammation involving the papillae without resulting in obliteration. He says that the papillary atresia cannot be attributed to a congenital narrowing, because certain embryologic investigations have shown that the tubules are devel-

oped from the wolffian ducts and do not develop separately from them and afterward unite with them. The fact that we find cysts in all parts of the kidney, including the papillae, does not, however, make it necessary to assume that the obstruction must be located in the papillae. The cysts of the upper tubules might extend into the papillary tract and displace the straight tubules and project into the pelvis.

In favor of the theory that the condition is a developmental malformation is the fact that other congenital malformations frequently coexist. The presence of congenital cystic liver in association with cystic kidney, which occurs in 19 per cent. of the cases (Moscowitz), is also significant of the embryonal origin of the condition. The cysts of the liver are ascribed by Moscowitz as due to the obstruction of afferent intracinar bile-ducts, and are evidence also of congenital origin. Other anomalies which have been found associated with cystic kidney are hypospadias, atresia, and absence of ureter, vagina, bladder, etc.; also hare-lip, spina bifida, or absence of extremities. There is now pretty general agreement among investigators that the condition is due to defect in development, which is explained somewhat as follows: The tubular structure of the kidney, including the glomeruli, the convoluted tubules, the loops of Henle and the straight tubules, to a considerable extent, originate by a development of tubules in the mesoderm of the embryo. The ureter, kidney, pelvis and an uncertain amount of the straight tubules in the pyramids develop from a tubular process which originates from the wolffian duct. The straight tubules grow out and meet the primitive vesicle, which becomes the glomerulus; and then later from this glomerulus the convoluted tubules and Henle's loops are developed (Brödel). In case this tubule growing from the wolffian duct fails to connect with the primitive glomerular vesicle, an obstruction occurs, resulting in cystic dilatation of the entire tubular system above the straight tubules. The extent of the process will depend on the relative number of tubules that fail to meet. If a large proportion fail to connect, then the cystic formation will be rapid and complete, and, no kidney tissue being left to eliminate urine, the patient will die. If, on the other hand, there be left comparatively large areas of healthy kidney tissue, enough for the elimination of uric acid, the patient may live for years and die from other causes. The presence of the increasing cystic tissue may finally so squeeze the intervening healthy tissue as to cause insufficiency, and the patient dies from this. This theory seems adequate to explain the facts as observed, and to be in every way more probable than that fetal nephritis involves the papillae. This view has lately been adopted by Berner.¹

Bunting, in a careful microscopic study of specimens from two cases, found that in these cases the urinary path could be opened from the glomeruli through to the pelvis of the kidney, and, therefore, added no evidence in support of the obstruction theory or a failure of two sets of tubules to join with each other. He believes that the primary cause of the trouble is the epithelial hyperplasia, which, so to speak, forces out the walls of the tubules. This theory does not satisfactorily explain, however, why we get cystic forms instead of epithelial growths, and needs further confirmation. Whatever theory of cystic kidney be adopted, we cannot help concluding that it is

CONGENITAL CYSTIC KIDNEY—LUND

1085

a developmental condition, a malformation rather than a new growth. A fact that speaks strongly for the malformation origin is its occasional occurrence in several generations of the same family, showing a tendency to inheritance.

Cystic kidney has oftenest been observed in the middle decades of life, but cases have been reported in the first and second decades as well. In the adult, the pathology corresponds in every way with that of the new-born except that the individual cysts are larger, as are also the entire kidneys. It becomes evident, therefore, that if our explanation is correct, we must assume that in case of cystic kidney in the adult, the condition has existed since birth but has not until later years given rise to symptoms that attract attention.

If our views of the etiology and pathology of the disease as given above are correct, they will furnish us an adequate explanation of the somewhat remarkable symptomatology and course of the disease. The most thorough and careful description of the course and symptoms which I have found is that of Milward of Birmingham, who divides the clinical history of the disease into three stages:

1. The stage of progressive enlargement of one or both kidneys without subjective symptoms. The renal enlargement is discovered, if at all, by accident. This stage may last from a few months to several years.
2. The stage of subjective symptoms and objective signs. This stage lasts from a few months to six or eight years, or even longer. The signs and symptoms are dependent on the size and weight of the tumors.
3. The stage of decreasing elimination of urine. In this stage appear the symptoms of uremia or cerebral complications. It lasts two or three weeks or a few months.

Males and females are affected in about equal numbers. The disease usually terminates fatally in the fourth, fifth, or sixth decade. Renal enlargement is rarely discovered before adolescence, and when the disease develops in infancy, the child hardly ever lives till the tenth year, so that the disease has been rarely reported between the tenth and thirtieth years.

The symptoms noted during the second stage are a dull, aching pain in the region of the kidneys, during both night and day, but usually worse in the daytime, especially if the kidney is movable. A large part of the pain, especially in the later stages, seems to be due to mobility of the kidney. There is tenderness on palpation or pressure, and occasionally the pain may be paroxysmal and very severe, with resulting prostration or examined post mortem present cysts filled with blood under high pressure, it is reasonable to suppose that some of the pain may be due to hemorrhage into the cysts. Occasionally, suppuration has taken place in one or more of the cysts and has required operation. Flatulence, headache, dyspepsia, vomiting, anorexia and constipation are frequently concomitant symptoms. It is an important and somewhat interesting fact that the examination of the urine often throws very little light on the diagnosis, a circumstance which contributes greatly to the difficulty of the latter. During the second stage and until the deformation of their functions almost perfectly. The specific gravity is usually low, below 1.010, and the amount passed is usually slightly increased, but may be diminished. There is usually only a slight trace of albumin, and often albumin is entirely absent. In the second stage,

it is never present in large quantities except when there is a great deal of blood. Casts are practically always present; leukocytes are common and often occur in large numbers. Pus may be present in acid urine. Blood is usually present in traces, and when there is hemorrhage into the cysts, may be poured out in such large quantities as to constitute attacks of hematuria. Bleeding may occur every few months, or once a year, or may never be sufficient to tinge the urine. Some blood, however, is always present, and this is significant (Milward).

The elimination of urea may amount to from 250 to 350 grains until late in the second stage; and it is not unusual when death occurs suddenly (as it often does in the third stage) for the physician to find to his surprise the cystic kidneys.

The symptoms of the third stage are those of uremia or some allied complication, such as cerebral hemorrhage, due to arteriosclerosis, and consist of headache, dyspnea, drowsiness, convulsions, paralysis and coma.

In the majority of cases the symptoms last from a few months to five or six years. Twenty-two and nineteen years, respectively, was the duration of symptoms in the longest cases noted. Ritchie, reporting on eighty-eight cases, found that in seventy-five, the average age at death was 45.3.

Of seventy-eight cases in which the symptoms were analyzed, thirty had renal symptoms apart from albuminuria, twenty having pains in the loins and abdomen. Sixteen had hematuria at some time. Seven had no kidney trouble, and no evidence of illness, but cystic kidneys were found post mortem. Eleven suffered, or had suffered, from edema; in ten the absence of edema was stated. In thirty-three the urine contained albumin, in nineteen a trace, and in eleven a considerable quantity. Vomiting or intestinal symptoms, constipation or diarrhea, was present in nineteen cases. Twenty showed anemia, cachexia or loss of flesh. Thirteen had dyspnea or some pulmonary affection. In twenty-one, tumor was discovered during life in one or both flanks.

A brief review of the literature shows us that those patients who have come under the surgeon's care presented themselves during the second stage for pain in the side, due either to the weight or to the mobility of the tumor. The surgeon finding the tumor operated, and, if it was large and malignant-looking, not infrequently removed it. The patient lived or died according to the presence or absence in the other kidney of sufficient healthy tissue to attend to the elimination of urea.

Several years ago, in cutting down in a case² of movable kidney, I found that I had a case of congenital cystic kidney to treat. I made an incision on the other kidney, and found that also was cystic, so, instead of removing the kidney in this case, I punctured the larger cyst, and sutured the kidney in place, with considerable relief of the symptoms, so that the patient (who was a nurse) was able to go back to work and lived in comparative comfort for many years.

My next experience (Case 4, reported below) was being called to see a woman who was subject to congenital cystic kidney, who had recently had a baby, and following that, had had infection of one of her

2. Lund, F. B.: Congenital Cystic Kidney, *The Journal A. M. A.*, Aug. 18, 1906, p. 479.

kidneys. This had been incised, and from the wound pus was discharging, and she had had a picket-fence temperature for something like six weeks. I cut down on the kidney, and found a congenital cystic kidney, with many of the cysts infected. Inasmuch as she was rapidly running down from suppuration and there was no way of draining all the separate cysts, I removed the kidney, hoping that the other kidney was not too much involved in the disease. She recovered from the operation and got well. When she became pregnant again, symptoms of swelling of the extremities, dizziness, headache, etc., appeared, and she had to have miscarriage induced twice. Then I removed the tubes, and she has been well and happy since—about five years. The other kidney—the right one—can be felt to be considerably enlarged and cystic at the present time, but it is not increasing much in size.

These experiences led me to make a study of congenital cystic kidney, the results of which were published in a paper read before the American Medical Association at its Boston meeting in 1906, from which I have freely quoted.

It is evident from the foregoing discussion that the disease is fatal from compression of the kidney-tissue between the cysts; and that while it may be practically impossible to cure the disease, it might be arrested at any given point if the growth and multiplication of the cysts could be stopped so that the kidney-tissue could be no further compressed between them. This Curtis and Kammerer have attempted to do, and I myself have done it rather inefficiently without knowing of their work, as in the case I referred to at the beginning of this paper. Last year, however, I had the pleasure of a visit from Professor Rovsing, who told me of his results in the treatment of this disease by puncture of the cysts; and under his direction, I was fortunate enough to be able to perform an operation on the right kidney of a patient then in the ward. I have since had the opportunity of the same patient, and on one kidney in each of two other patients, and I am so pleased with the results that I am glad of the opportunity of reporting them.

Rovsing's operation consists in exposing the kidney through the ordinary oblique incision in the loin, and puncturing the cysts on its surface as far as they can be reached by retracting the wound; and it will be found when you try it, that a very large area of the anterior and posterior surface and posterior border of the kidney can be reached. As the cysts are punctured and the contents flow out, the kidney is much diminished in size, and may be so reduced that one pole and then the other may be delivered from the wound. Then, with the kidney held in the left hand, the larger cysts and bunches of cysts may be felt and the hollow needle run into them. Care should be taken to avoid the areas of normal kidney-tissue wherever they can be seen and felt. There will be very little bleeding unless these areas of tissue are punctured. A kidney which is six, or eight, or even ten times the normal size may by this means be reduced until it is of a very decent size, say perhaps twice the size of a normal kidney. Then the kidney can be replaced in the abdomen, and the wound closed without drainage. It seems like a formidable procedure, but it is not so; and the surprising thing about it is, that the kidney not only is of smaller size when it is replaced in the abdomen, but that after a temporary increase in size, it remains small and no longer troubles the patient by its weight and dragging sensations.

Rovsing³ has reported three cases in which this operation was performed. In his first case, reduction in the size of the kidney was permanent, and the albuminuria which was noted before the operation disappeared. The patient lived in comfort for some time, and then died of uremia following fever. In Rovsing's second case, the pain and dragging from an enormous kidney was relieved by this operation, and the patient was well for two and one-half years after the operation. The albuminuria diminished, the urinary excretion tripled, and the urea excretion doubled.

In Rovsing's third case, an enormous kidney was reduced in size, the twenty-four-hour quantity of urine increased, the excretion of urea increased, the patient's appetite improved, and the patient's color became healthy. Rovsing says:

It is to be noted that in these cases, the pain disappeared and renal function was reestablished to a striking degree. . . . There is but one explanation for this unmistakable improvement in the activity of the kidneys. Normal renal tissue is present among the cysts. The pressure of the latter when full and tense inhibits renal function, which is resumed when the mechanical effects of pressure are removed. The improvement of the patient is also thus accounted for. It is not claimed that the disease is cured by the operation, or that its ultimate fatal issue is more than just postponed. The disappearance of the pain, however, the prolonged and striking restoration of renal activity, the simplicity of procedure and the absence of shock after the operation should constitute a sufficient incentive to attempt this treatment as herein outlined in every case of this type.

My own cases go far to bear out the statements of Rovsing in regard to his operation. I will give them as follows:

CASE 1.—M. M., negress, aged 37, married, who had had eight children and five miscarriages, was admitted to the Boston City Hospital in June, 1910. In May, 1912, lumps were found on both sides, which were diagnosed by her physician as kidney tumor. Appetite was good; bowels constipated; no urinary symptoms. The patient had noticed the lumps for three years. She appeared to be well developed and nourished. Heart, lungs and extremities were negative. There was marked enlargement of both kidneys. Function of left kidney was not good, and operation was advised to relieve pressure.

Cystoscopic examination (Dr. Binney) revealed bladder normal and ureters normal; catheterized for 15 cm.

Functional test: Phenolsulphonephthalein: Color appeared from right ureter at end of 25 minutes; from left, ?

Right, first hour, 0; second hour. . . . 5 per cent.
Left, first hour, 0; second hour. . . . 0 per cent.
Bladder urine 18 per cent.

Total 23 per cent.

No function of left kidney; very low normal function in right.

June 24, 1912, I made a left lumbar incision. Kidney was exposed and found enlarged to the size of a baby's head, and to consist of cysts. No kidney tissue was found. The cysts were punctured, with discharge of straw-colored fluid until the kidney was small enough to deliver through incision. I continued to puncture the cysts, both deep and superficial, until the kidney was reduced to twice normal size. It was then replaced, and the abdomen sewed up tight. The patient made a good recovery, but tests made about two weeks after the operation showed no apparent change in the kidney function since the operation. The patient was discharged, July 11, after being told to come back in September for an operation on the other kidney.

3. Rovsing, Thorkild: The Treatment of Multilocular Kidney Cystoma (Congenital Cystic Kidney) by Means of Multiple Punctures, *Am. Jour. Urol.*, 1912, viii, 120.

CONGENITAL CYSTIC KIDNEY—LUND

1087

The urine examination, July 10, follows:
Pale; cloudy; specific gravity, 1.004; acid; slight trace of albumin; no sugar; much pus; few epithelial cells.

The patient returned to the hospital, April 16, 1913. She stated that after leaving the hospital, last July, she felt weak. Complained of pain "across the small of the back" when bending over or when fatigued. Has slept well; good appetite; no nocturia; no trouble in passing water; has cramp-like pains in left side of neck, left arm, left shoulder, and in left leg; menses regular; no leukorrhea; constipated. During the previous month, the patient had felt considerably weaker, and complained of headache and languor.

On physical examination, the patient presented in right upper quadrant an irregular mass extending to middle line and to level of umbilicus, and above to costal border. The mass could easily be seen with patient at ease, moving with respiration. On palpation with one hand on abdomen over mass and other hand in flank, the mass could be moved about freely, with no apparent pain.

April 17, I made a loin incision. The kidney was found much too big to be delivered through the wound. No good kidney-tissue could be seen; nothing but honeycomb cysts of all sizes could be seen or felt in the kidney. I punctured the cysts with a trocar, and much clear and cloudy fluid (not urine) was withdrawn. After a considerable number of cysts had been punctured and contents evacuated, the kidney was delivered and puncturing of the cysts continued. After reducing the kidney greatly in size, I put it back in position, and closed the wound. Eight days after the operation, the patient was comfortable and passing considerable urine. The mass could be felt, but it was considerably smaller than at entrance, and the patient was discharged May 1.

I saw this patient in the autumn of 1913. She was in good condition, and both kidneys could be felt, but they were not nearly so large as before operation.

CASE 2.—F. S., a woman, aged 35, married, two children, had had a hard time with the first child, and was miserable for five or six years; suffered from anemia; had pain in right side; seemed as if stomach was floating.

Examination showed a very large mass in the right loin extending down on to the brim of the pelvis. The left kidney could also be felt. The mass in the right loin felt as if cystic. Probable diagnosis was made of congenital cystic kidney, and Dr. Loder examined the urine from both kidneys and reported as follows:

Bladder Urine: Very pale. Specific gravity, 1.005. No albumin. No sugar. Neutral. Urea, 0.2 per cent.
Right Urine: Specific gravity, 1.005. Trace of albumin. Urea, 0.2 per cent. Sediment: Blood and epithelium from catheterization. No pus. No casts or renal cells.
Left Urine: Specific gravity, 1.005. Trace of albumin. Urea, 0.3 per cent. Sediment: Blood and epithelium from catheterization. No pus. No casts or renal cells.

Functional Test:
Right: Time, 9 minutes. 84 c.c...22 per cent.
Left: Time 11 minutes. 65 c.c...22 per cent.
Leakage about catheters..... 8 per cent.

Total 52 per cent. (1 hour)
Cystoscopy: Trigon shows numerous small, slightly congested areas, slightly elevated. Right ureteral orifice, negative. Left orifice is encroached on on one lip by one of the above-mentioned minute elevations; otherwise normal in size and motion. Catheters passed without difficulty to kidney.

Conclusion: No infection or tumor of kidney. No impairment of function of left kidney.
At the Deaconess Hospital, Aug. 29, 1912, she was placed in a left lateral position for operation on the right kidney. Then the tumor could not be pressed up into position of the kidney, and some doubt was felt as to the diagnosis. An abdominal incision was therefore made at the outer border of the right rectus for exploratory purposes. The left kidney was found to contain numerous large cysts, and the right kidney numerous cysts of various sizes, and a very large cyst at its lower pole. The patient was replaced in the lateral position, and an incision made from the tip of the twelfth

rib down and forward to the spine of the ilium. The kidney was dissected out and drawn out of the loin. A very large cyst, which must have contained 4 ounces at the lower pole, was opened and cut away. The other cysts all through the kidney were punctured with a trocar and opened with a knife. There was a good deal of healthy kidney tissue between the cysts. The kidney was reduced to about one-third of its former size, and was sutured to the spinal muscles. In puncturing the cysts, the pelvis of the kidney was opened with a knife, and this opening was closed by suture. A cigaret drain was passed into the loin and the wound sutured to it.

The patient had a high temperature for four or five days, and on September 5 I found pus in the lower angle of the wound. I opened it up, and found a cavity containing about 2 ounces opposite the lower pole of the kidney.

After operation, there was a large increase in the amount of urine passed. The patient made a good recovery, and during the winter and spring of 1912-1913 she gained in flesh, color, and general appearance. Oct. 15, 1912, Dr. Loder made a phenolsulphonephthalein test, as follows:

Right: Time, 9 minutes. 35 c.c....24% Urea, 0.4%
Left: Time, 9 minutes. 40 c.c....22% Urea, 0.3%
Leakage 10%

Total 56%
This test as compared with that before the operation shows a doubling of the amount of urea in the excretion of the right kidney.

I saw this patient in June, 1914—that is, nearly two years after the operation—and she is in excellent health. She has good color, and looks much better than when she was operated on. The right kidney (the one operated on) could just barely be felt. The left kidney could also be felt and is a little enlarged.

The urine examination, June 15, 1914, was:
Slightly cloudy; acid. Specific gravity, 1.010. No sugar. Slightest possible trace of albumin. Sediment: Few small round renal cells. No pus, blood or casts.

CASE 3.—C. S., woman, aged 41. One child, instrumental delivery twenty years ago. For about a year, had been growing thin and weak; complexion had become sallow; and she had suffered considerable abdominal pain, especially in the flanks. She had consulted her physician, Dr. C. H. Miller, and sent her to me. He had discovered tumors in both flanks, and on examination, I found her thin and pale. There was very marked enlargement of both kidneys, especially of the left.

Urinary examination by Dr. I. J. Walker, was as follows:
Specimen from bladder: Cloudy. Specific gravity, 1.014. Acid reaction. No sugar. No bile. Slight trace of albumin. Sediment: Some blood; some small and large renal cells; a few bladder-cells; a few leukocytes; no casts.

Cystoscopic examination was as follows: Bladder walls normal in appearance. Right and left ureteral orifices normal in appearance. Flow from right kidney about five times greater in amount than that from left kidney. Specimens showed the following:
Right: Pale. Slight trace of albumin. Sediment: Many small round renal cells, and a few large round renal cells. Rare normal blood corpuscle. Few hyaline casts in about twenty fields.

Left: Much normal blood. Many small round renal cells, and a few large round renal cells. A few leukocytes. One hyaline cast found.
Functional test: Color appeared from right kidney in twelve minutes; from left, in seventeen minutes. Urine collected in one hour showed: right kidney, 20 per cent.; left kidney, 2 per cent.

Rovsing's operation was done at the Boothby Hospital, March 29, 1913: Oblique left lumbar incision. Enormous polycystic kidney found. A very thorough puncture of the kidney was done with a moderate-sized

aspirating needle, running it thoroughly all through the kidney wherever a cyst could be found. The cysts on the surface appeared to extend out into the surrounding connective tissue. By puncturing the cysts, marked diminution in the size of the kidney was made, and it was finally drawn outside the abdomen. When I finished, the kidney was about twice normal size, and about one-fourth the size it was when we started to operate. In puncturing the cyst in the upper pole, a moderate amount of blood was obtained. Having punctured all the cysts we conveniently could, the kidney was replaced and sutured with chromic catgut sutures. A cigaret drain was placed in the lower angle of the wound. The patient bore the operation well.

Before the operation, the patient was passing from 30 to 45 ounces of urine; the following is the report of the urine examination made two days after the operation: Cloudy. Acid reaction. Specific gravity, 1.008. No sugar. No bile. Slight trace of albumin. Sediment: Some normal blood (about 60 corpuscles to a field), a few small round renal cells; occasional large round renal cells; a few bladder cells; rare ureteral cells; much amorphous urates.

The amount of the urine increased; the kidney increased somewhat in size and afterward diminished, and has since remained so it can hardly be felt to have increased in size. The patient has made a considerable gain in flesh, strength, and general appearance. No urethral catheterization has been done since the operation.

I saw this patient in June, 1914, a year and three months after the operation. The left kidney (the one operated on) could just barely be felt. The right is certainly as large as the left was before operation. Her face has filled out, and she feels much better. She is going to come in the autumn to have the other kidney operated on.

Examination of the urine, June 15, 1914: Slightly cloudy. Acid. Specific gravity, 1.006. No sugar. Slight trace of albumin. Sediment: Many bladder-cells. Considerable number of leukocytes. Few small round renal cells. No blood or casts.

CASE 4.—C. J., a young married woman, seen in consultation with Dr. Bateman at the Somerville Hospital, in 1907. Her father had died at the age of 50 with cystic kidneys. She had been trained as a nurse, and had recently married. Four months before, she had had a baby, which was born in normal fashion. After the baby's birth, the patient had had a high temperature and complained of pain in the right side. Three weeks before, a surgeon had been sent for, who found a tumor in the region of the left kidney, made an incision, and found several cysts, some of which contained pus. After the operation, the patient had a temperature from 100 to 103, and suffered pain, although she passed a fairly normal amount of urine.

I found a discharging sinus in the left side, and a large tender kidney on that side. The right kidney was also palpably enlarged. June 29, through the sinus, I found a large kidney studded with cysts of various sizes and colors, some of them containing pus. It had been recognized that suppuration from that kidney was the cause of her symptoms, and that it was therefore necessary to remove the kidney. This was done, the pedicle being sewed with catgut. Considerable pus escaped from several cysts. Her pulse was about 140 during operation. July 2, she was reported in good condition.

I saw the patient again, two years after the operation just reported. In the meantime, she had had to have two abortions done by Dr. Bateman, as she had become pregnant and the condition of her kidneys would not allow her to go through pregnancy. She had recently become nervous and suffered a good deal of pain in the left side of the pelvis. Examination showed the uterus movable. The left ovary could be felt to be prolapsed, and this was thought to cause her pain. Median laparotomy was done. The prolapsed left ovary and tube were removed, and the right tube was removed, the right ovary being left behind. This was done to prevent future pregnancy. The right kidney could be felt very much enlarged and cystic. The patient made a good recovery.

As a result of my experience in these four cases, although it is not a large one, I am inclined to think that Rovsing's suggestion of a thorough, systematic puncturing of all the cysts until the kidney is brought down to near normal size is a distinct advantage to our therapeutics in these cases; and I am inclined to feel that I shall perform it in all cases in which the kidney secretion is not too greatly crippled so that any operation might bring on uremia. I believe that in the present state of our knowledge, it is wise, in case both kidneys are involved, to operate on only one kidney at a time. Even if we cannot absolutely cure our patients and make them as good as if they had never been subject to the disease, if we can relieve them of pain and dragging, as I think it has been demonstrated that we can, improve their health, weight, appearance and color, and practically arrest the disease, it seems to me that we can accomplish a good deal. And we must give to Rovsing the credit for having improved and systematized the method of puncture of the cysts—which had been tried in a half-hearted way by others, including myself—until it has a really distinct therapeutic value.⁴

527 Beacon Street.

ABSTRACT OF DISCUSSION

DR. D. N. EISENDRATH, Chicago: Dr. Lund's paper is an example of what modern pathology has taught us. Formerly we thought that a congenital cystic kidney was only of interest to the pathologist, but now that we have come to see it under various clinical forms, it becomes of great interest to the surgeon. These cases, formerly regarded as absolutely hopeless, are now amenable to such an operation as Rovsing's for at least temporary relief and the prolongation of the patient's life for a number of years. I differ with Lund only with regard to the priority of this operation. Dr. Wither- spoon of Butte, Mont., at our meeting at St. Louis first presented this operation in this country. I think Dr. Wither- spoon deserves equal credit with Rovsing for this, having worked independently of him. The clinical picture is one every general practitioner as well as the surgeon should know. Many cases show first of all marked symptoms of uremia. In a case of uremia think of the possibility of a congenital cystic kidney as a basis and examine the abdomen. In a comparatively early period you will find a kidney which you can recognize as of the congenital cystic variety; the kidney is lower and easily palpated for that reason. It has a lobulated, soft surface. I made the diagnosis in one case three years ago, first in one kidney and then watched

CONGENITAL CYSTIC KIDNEY—LUND

1089

the development of the condition in the opposite kidney. The same condition confronted us in that as in one of Dr. Lund's cases, namely, pregnancy. It was necessary to interrupt pregnancy on account of the threatened uremia which would have undoubtedly ensued. The second clinical symptom of this kidney condition is hematuria; a fair proportion of cases of severe bleeding from the kidneys is probably due to such a condition. In every case, congenital cystic kidney appears as a tumor. A large, soft, lobulated tumor of the kidney accompanied with hematuria should be considered among other causes, as due to this condition. It has been supposed to be useless to operate in these cases because they are bilateral, but as Dr. Lund has pointed out, the benefit from such operations is so great that we ought not to abandon them. At a recent meeting of the American Urological Association Dr. Barnett of Fort Wayne reported one case of his own and quoted, among others, four cases of Dr. Ochsner, in which they removed such a kidney, thinking that the condition was unilateral. This condition is always bilateral and if one kidney is ahead of the other in the development of the condition the other will surely catch up with it, and it is perfectly useless to take out one kidney. The condition is due to lack of union of the proximal and distal portions of the urinary tract.

Dr. A. L. CHUTE, Boston: In such experience as I have had the condition has invariably been bilateral. In Walker's new book on this subject he gives some figures concerning the relative frequency of unilateral and bilateral polycystic kidneys. He says that in only one case in thirty is the disease confined to one side. This too small a proportion to allow one to consider nephrectomy in these cases. The last case that I saw illustrates the other point—that of the infection of these kidneys. This patient, a woman of 47, had a history of some renal trouble six years before. This was supposed to be Bright's disease and she improved considerably under treatment. The latter part of last December she had an attack of pain, first in the right side, then in the left. She had a moderately elevated temperature with these attacks. I easily could feel a mass in her left side. I thought this was due to hematogenous infection and that it would quiet down without any interference. The temperature kept up and I operated on this kidney and found two pockets of pus which I thought were abscesses in the cortex, and which I opened. After the operation, the temperature kept up and the patient became apparently uremic and died four days later. Necropsy showed that there were several other infected cysts in the kidney I had operated on, and that the other kidney was also polycystic and contained likewise a number of suppurating cysts. The question has been raised as to the advisability of removing these kidneys when they have become infected.

Dr. ARTHUR DEAN BEVAN, Chicago: I have had six or eight of these cases under observation. The first point I make is that this condition is not always bilateral, or if it is the condition varies so on the two sides that nephrectomy is not entirely eliminated from consideration. I think it is in the majority of cases, but I have had two cases in which we made a nephrectomy for polycystic kidney with practically permanent results. The first case was one in which a severe hemorrhage from the kidney. The hemorrhage was extreme. The man was very anemic. It was before the days of the phenolsulphonaphthalein test and at the time we were using cryoscopy. The cryoscopic examination of the blood, with that as a guide I did not hesitate to remove an enormous polycystic kidney on the right side from which the blood came. The man made an uneventful recovery and a year later I saw him and he was perfectly well. Another case some time later, in a woman, was much the same condition, with recovery, so that, although in the same majority of these cases the condition is bilateral, and a nephrectomy certain number in which it is unilateral, and a nephrectomy is not entirely excluded. In a number of cases in which I have found extensive polycystic conditions in both kidneys

at the time of the exploratory operation, I have been surprised to find, when a purely exploratory operation has been made, that the patients have recovered and have lived for years. The condition slowly progresses and the finding of this polycystic degeneration does not mean anything like an immediate menace to the patient's life. I believe that the work done by Rovsing and Dr. Lund shows a definite and distinct advance. I have not employed this operative procedure, but in the next case of polycystic degeneration of the kidney with which I have to deal I shall certainly employ the Rovsing-Lund procedure. I believe it is perfectly rational and a common-sense proposition and that it does hold out definite benefit to the patient.

Dr. ALBERT J. OCHSNER, Chicago: I wish to bring out two practical points. In this class of cases the patient's condition will be enormously improved by a proper diet. A patient who was a perfectly useless suffering invalid has been able to teach school the entire year with perfect comfort by simply confining herself to the food that one would provide for any patient who has not enough active kidney tissue to do the physiologic work; namely, milk, buttermilk, cooked vegetables, fruits and fruit juices. In the place of meat these patients should eat from two to six eggs each day. By adhering to this diet one will be amazed at the improvement in the condition. Three twenty-minute roentgenizations will produce sterility. Why should the tubes and ovaries be removed in a case in which sterility can be obtained in this safe and simple manner? I have a patient at present under this treatment. This, of course, applies to every female in whom, to prevent uremia, sterility must be secured. In order to make absolutely sure I gave this patient six exposures directly over the ovaries on successive days and feel perfectly certain that pregnancy cannot occur.

Dr. F. W. McRAE, Atlanta, Ga.: I operated in one case of congenital kidney which was certainly unilateral. I came on the kidney accidentally in doing an operation for acute appendicitis on a patient in September, a year ago. The patient was brought in in a rather extreme condition and I found a large cystic tumor. I was not familiar with Dr. Rovsing's work, though I knew of Dr. Lund's. I felt it was safer to make another incision and drain the kidney. The exploration enabled me to examine the opposite kidney and it seemed perfectly normal. The drainage lasted over three months and during that time I had one of our best genito-urinary men make cystoscopic examinations and try to find communication between the kidney and bladder above and below. There seemed to be no connection. In January I removed the kidney. The boy was 14 years old and since that time has increased in weight from about 70 to 110 pounds and is in perfect health. The cyst after draining became infected with a pyocyanus infection, and the boy's condition became bad, so that it was absolutely necessary to remove the kidney, which the father hesitated to have done. This case proved beyond question that some of these patients may be operated on and permanently cured.

Dr. F. B. LUND, Boston: I would not deny the existence of unilateral congenital kidney cyst, but in all necropsies that I have seen they have been bilateral. So large a proportion are bilateral that we should not think of nephrectomy without inspection to ascertain whether the other kidney is normal. Nephrectomy should be done unless there is sufficient kidney function in the diseased kidney to make it worth saving, in which case Rovsing's operation could be done on the diseased kidney, even if the other kidney is healthy. With regard to the use of Roentgen rays for producing sterility, I did not take out the ovaries to produce it; I tied off the tubes and removed one of the ovaries because it was somewhat cystic.

The Source of Dogmatism.—Gross ignorance produces a dogmatic spirit. He who knows nothing thinks that he can teach others what he has himself just been learning.—La Bruyère.

FURTHER STUDIES OF THE THOMPSON-
McFADDEN PELLAGRA COMMISSION

A SUMMARY OF THE SECOND PROGRESS REPORT *

J. F. SILER, M.D.

Captain, Medical Corps, United States Army

P. E. GARRISON, M.D.

Passed Assistant Surgeon, United States Navy

AND

W. J. MacNEAL, M.D.

NEW YORK

The First Progress Report of the Thompson-McFadden Pellagra Commission was published in successive numbers of the *American Journal of the Medical Sciences* from April to September in 1913, and a summary of this material appeared in THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Jan. 3, 1914. The chief conclusions from the first year's work were stated as follows:

1. The supposition that the ingestion of good or spoiled maize is the essential cause of pellagra is not supported by our study.

2. Pellagra is in all probability a specific infectious disease communicable from person to person by means at present unknown.

3. We have discovered no evidence incriminating flies of the genus *Simulium* in the causation of pellagra, except their universal distribution throughout the area studied. If it is distributed by a blood-sucking insect, *Stomoxys calcitrans* would appear to be the most probable carrier.

4. We are inclined to regard intimate association in the household and the contamination of food with the excretions of pellagrins as possible modes of distribution of the disease.

5. No specific cause of pellagra has been recognized.

It was decided that our efforts during the second year should be devoted especially to a continuation of the field study of pellagra to see whether a further and more intensive investigation of the occurrence and distribution of the disease would yield further evidence confirming our ideas of its infectious nature and additional data indicating the particular manner of its transmission from person to person. The field work of the first year had laid a good foundation for further and more detailed observations in the same territory during the second year. At the same time, however, the attempts to transmit pellagra to animals, the studies of the blood and of the intestinal micro-organisms, and the observations on treatment of pellagra were continued. The detailed accounts of certain portions of this work are to appear in early numbers of the *Archives of Internal Medicine*, and some phases of the work are illustrated in an exhibit displayed at the present session of the American Medical Association.

At the end of 1912 we were able to present records of 282 cases of pellagra in Spartanburg County. In 1913 this number was increased to 847 cases which had occurred in the county and concerning which we have recorded more or less detailed information.

The geographical distribution of pellagra in Spartanburg County has continued to be very uneven, the large active foci of the disease being in and near the large centers of population and especially in the industrial communities surrounding the cotton mills. The agricultural population seemed to be, on the whole, much

less affected by the disease. In 780 of these cases we know the race of the patient and the place in which he lived at the time the disease was recognized; 680 of them were white and 100 negroes, a morbidity rate of 119 per ten thousand among the whites and 38 per ten thousand in the negroes. This ratio of 3:1 is not considered to be necessarily indicative of a relative racial resistance to pellagra in negroes, but rather as the end-result of the influence of several factors. In Spartanburg County about one-fourth of the entire population resides in cotton-mill villages, and it is in these communities, made up almost entirely of white persons, that pellagra is most prevalent. The congestion of population in these communities in conjunction with the poor hygienic conditions under which the people live, as compared with the relative isolation of the bulk of the colored population on farms, appears to us to be an important factor governing racial distribution in Spartanburg County.

The age and sex was ascertained for 740 of the pellagrins, 528 being females and 212 males. The distribution according to sex and age at time of record showed much the same features as were noted in 1912. There was no case under the age of one year and only one, a negro baby, in the second year.¹ In the third year there were 12 cases and between the ages of 2 and 10 years no less than 94 cases, nearly equally divided between boys and girls. Among females, those between 12 and 17 years of age were relatively least frequently affected by pellagra, the age period under 2 years being excepted. In females beyond the age of 17 the pellagra morbidity rose abruptly so that the number of recorded cases in the age period from 20 to 44 equals about 2.5 per cent. of the women now present in the county in that age period, a ratio much higher than was observed in any other group of the population. Women beyond 44 years of age were somewhat less frequently affected by pellagra. In males the number of cases was large from the third to the eighth year, then somewhat less until the lowest morbidity was reached at puberty and maintained from the fourteenth to the twenty-first year, after which there was a gradual increase to old age, the rate after 50 being approximately equal to the rate for females of the same age.

The remarkable features of the data seem to be the almost complete absence of pellagra under the age of 2, its very slight prevalence for the five years following puberty in both sexes, and its slight prevalence in adult males under 50 years of age; further its enormous prevalence in adult females, somewhat less marked prevalence in children of both sexes from 2 to 10 years of age and the almost equally marked prevalence in old age in both sexes. These features of the age and sex distribution we believe to be due in part to differences in individual resistance to pellagra and in part to differences in exposure to the disease, especially by association with other pellagrins.

The data in regard to occupation are available for 726 pellagrins, of whom 413 lived in cotton-mill villages and 313 lived elsewhere. Of those not living in cotton-mill villages (313), more than half, actually 171, were women engaged in housework exclusively; there were 25 children without occupa-

* From the New York Post-Graduate Medical School and Hospital.
* Read before the joint meeting of the Section on Preventive Medicine and the Section on Pharmacology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, June, 1914.

1. We have seen a few definite cases of pellagra in very young children outside of Spartanburg County, one patient from Laurens, S. C., 1½ years old, and one at Clinton, S. C., 13 months of age. We have records of the cases of several other patients less than 2 years old which have been reported to us by reliable observers.

tion; 37 farmers; and the remaining 60 pellagrins represented 19 different occupations, among them 5 merchants, 3 machinists, 1 college student, 1 butcher, 1 postmaster, 1 railroad fireman and 1 printer. Of the 413 pellagrins in mill villages, 133 were women engaged exclusively in housework; 96 were women without occupation; and 110 were women working part or all of the time in the cotton mills. The 71 adult males were practically all mill hands. The remarkable feature of the occupational study seems to be the lack of definite connection between occupation and pellagra. Although the disease was most prevalent in the families of cotton-mill workers, more than half of the cases in these industrial communities were in women and children who never worked in the mills. The suggestion that housework as an occupation favors the development of pellagra is weakened to some extent by the fact that women mill workers were slightly more subject to the disease than the housekeepers in the same mill villages, when due regard is given to the total number of individuals thus engaged. Nevertheless it does seem to us that the high pellagra morbidity in women, children and in old persons of both sexes points to the home as the place where the disease originates in most instances.

The question of the frequency of association between individuals developing pellagra for the first time and persons previously suffering from the disease was suggested by the work of 1912. During 1913 a complete data secured concerning the population of six mill villages have made possible a study of this question. In this population of 5,514 persons there were 115 cases of pellagra incident in 1912 and 1913. In only 19 of these 115 cases did we fail to find antecedent pellagrins living in the same house or next door, and in 7 of these 19 instances the incidence of close association with a preexisting case in more than 80 per cent. of all new cases in these six villages is the most striking feature of this study of association, and it strongly suggests that association is a factor in the spread of pellagra of much greater importance than has previously been thought to be the case. The essential elements in this association have not been fully examined into as yet. Considerable attention is being devoted to ectoparasites, such as lice and bedbugs, as well as to contact and food contamination as possible factors.

An important feature of the work in 1913 has been the house-to-house study of all the population of the mill-working class in six representative mill villages in Spartanburg County, during which the vital statistics of each person and the food habits of each family were recorded. The data recorded in this way cover a population of more than 5,000 people and have made possible approximately accurate statistical studies of the correlation between the occurrence of pellagra and various other ascertained factors. Thus it was found that of the 3,135 persons eating corn meal daily, 98, or 3.1 per cent., were pellagrins, while of the 681 using this food rarely or never, 41, or 6 per cent., were pellagrins. We have analyzed these data in regard to the use of shipped corn meal, local corn meal, any corn meal, fresh meat, canned (tinned) foods, eggs and milk, without discovering any indication that the more frequent use of any one of these foods is associated with an increase in pellagra which

would suggest a causal relationship. Those who used meat daily and those who used milk rarely or never did seem to be somewhat more subject to the disease, but the correlation was far from complete. In fact, we found many cases of pellagra among people abstaining from fresh meat altogether, and several cases in persons taking sweet milk or buttermilk regularly once or even twice a day. Our attempt to discover in this way the essential pellagra-producing food or the essential pellagra-preventing food has not been crowned with success and the evidence suggests, to us at any rate, that neither of them exists in the dietary of the population which we have studied.

In this same population our recorded data have enabled us to ascertain whether or not there was any distinct tendency for new cases of pellagra to develop in close proximity to preexisting cases. For the purposes of this study the population of these villages was divided into three zones. The first zone included all persons living in the same house with a preexisting case of pellagra; the second zone all persons living next door to a preexisting case; and the third zone all persons in the same village living at a greater distance than next door from a preexisting case. The result of this study indicated that of the 819 persons in the first zone, that is, living in the same house with a preexisting case of pellagra, 54, or 6.59 per cent., acquired pellagra during the two years 1912 and 1913; in the second zone 1.72 per cent. acquired the disease and in the third zone only 0.52 per cent.

The correlation shown in this study between the incidence of new cases of pellagra and the proximity of domicile to preexisting cases was more striking than we had been led to expect by the results of our first year's work, and it appears to emphasize the significance of very close relationship between the primary and secondary case, such as is provided by actual residence in the same household or in adjacent houses. From the viewpoint of the possibility of transmission of pellagra by blood-sucking insects, one result of this observation has been to direct attention to those insects most intimately domiciled with man, such as the louse, flea and bedbug, rather than to winged blood-sucking insects with a considerable range of flight.

We are confident that such a remarkable indication of the importance of proximity could not have been disclosed except by the intensive study of the disease in the same locality over a long period of time. Certainly the work of our first year did not reveal it. It seems to us that the conclusion is now clearly warranted that in these mill villages pellagra is in some way transmitted to non-pellagrous persons from a preexisting case and that one of the important factors in this transmission is residence in the immediate neighborhood of a pellagrin.

Another feature of our field work in 1913 has been the survey of communities offering marked contrasts in certain particulars. All the mill villages of Spartanburg County were found to be endemic centers of pellagra. A careful survey of the disposal of human excrement, one in Oconee County and the other in Chester County, S. C., failed to disclose any cases of pellagra which had certainly originated in these villages, although cases which had originated elsewhere were present. In these villages every house was provided

with a water-carriage flush closet connected with a sewer and this seemed to us to be their most important distinguishing characteristic. In the city of Spartanburg, S. C., the active foci of the disease were confined to those sections of the city in which unscreened surface or pail privies were in use. Of the 241 cases in the city of Spartanburg itself, for which data on disposal of sewage were available, it was found that 230 were using unscreened surface or pail privies. In only eleven instances, or 5 per cent. of the total, was a water-carriage system of disposal employed, and several of these cases arose in sections of the city where unscreened surface privies were in use by their neighbors, some of whom were pellagrins. In several other cities we have learned by more superficial surveys that pellagra is far more prevalent in the unsewered sections than elsewhere. In certain hospitals for the insane we have ascertained that pellagra is usually most prevalent and persistent in the wards housing untidy patients.

All these observations have compelled us to regard inefficient methods for disposal of human excrement as an important epidemiologic feature of those communities in which pellagra is endemic and have led us to recommend the installation of water-carriage systems of sewage disposal as a prophylactic measure against this disease.

Our extension studies beyond Spartanburg County have also included a very complete survey of one village, the peculiar topography of which was of great interest. One portion of this village was near a large pond and nearly every family in this section had suffered from tertian or estivo-autumnal malaria. Another portion of the village was on a swiftly running stream, while the remainder was located on a rather steep hillside. Our survey showed that malaria occurred almost exclusively near the pond, but that dysentery, typhoid fever and pellagra had been endemic in all three sections of the village without evident regard to topography.

These studies were also extended to a large island off the coast of South Carolina, the distinguishing characteristic of which was the absence of streams in which *Simulium* could breed. Pellagra was found to be endemic on this island. In May, 1913, one member of the commission and Mr. A. H. Jennings of the U. S. Bureau of Entomology investigated the epidemiology of pellagra in Texas. Our investigations were undertaken in the so-called Panhandle in the northwestern part of Texas where the rainfall is very slight and where running streams are remarkably scarce. In this region we found cases of pellagra originating. *Simulium* was unknown in this section and the nearest possible breeding places for insects of this genus were from 60 to 125 miles away. It was quite impossible that *Simulium* could have been concerned in the etiology of these cases. These and other observations to be published at a later date have further confirmed us in the conclusion based on our investigations of the prevalence, distribution and habits of *Simulium* in Spartanburg County, namely, that in the territory studied, flies of the genus *Simulium* did not fulfill the necessary conditions to serve as an efficient transmitter of pellagra.

The laboratory studies during 1913 included the inoculation of numerous monkeys, *Macacus rhesus*, with filtered and unfiltered suspensions of material from pellagrins, including saliva, duodenal fluid, feces,

tissues from the pharynx, stomach, intestines, brain, spinal cord, blood and lymph from the cutaneous lesions. In addition, monkeys were repeatedly subjected by Mr. A. H. Jennings and Mr. W. V. King to the bites of stable-flies (*Stomoxys calcitrans*) which had been allowed to bite pellagrins, these biting experiments being continued as long as the flies could be kept alive. A considerable proportion of these monkeys died with symptoms of dysentery late in the season and in each case a careful necropsy, including histologic study of the various organs, has been made by Dr. Paul A. Schule. This work has failed to disclose any conclusive evidence that pellagra had been produced in these animals.

The bacteriologic work was directed particularly to the discovery of specific serologic or other allergic reactions on the part of pellagrins toward the various bacterial strains isolated from the intestine. Approximately one thousand bacterial strains have been isolated and studied in this way, but the results of this work have still been inconclusive.

The studies of the cytology of the blood by Dr. O. S. Hillman and Dr. Schule have not disclosed any constant abnormality. A lymphocytosis was observed in approximately 75 per cent. of the cases examined by them.

Heredity as a factor in pellagra has been studied by Dr. C. B. Davenport and Dr. Elizabeth Muncey in collaboration with us. The study of family histories gave some indication of inherited susceptibility to pellagra, but no evidence of inheritance of the disease. Furthermore the apparent transmission of the disease from a woman to her daughter-in-law seemed to be about as common as to her own daughter, provided living conditions and associations were similar, so that even inherited susceptibility cannot be considered as established. This work is being continued this year.

Concerning treatment and prognosis we hope to make a more complete statement at a later time. The fourteen pellagra patients transported to New York by us in 1912 all returned home free from active manifestations of the disease. Two of them died during the following winter of other ailments and eight others have shown recurrent manifestations of the disease, three of them in a severe form. Three cases remained free from recurrence in 1913 and one has not been traced. We are inclined to regard the results of hygienic and dietetic treatment in adults as very comparable to those in tuberculosis, that is to say, the immediate results are often good and the disease appears to be arrested, but on return to former environment and living conditions, recurrence and further progress of the disease is to be expected in the majority of the cases. In children, on the other hand, permanent recovery at home without special treatment is the rule.

SUMMARY

1. The large active foci of pellagra in Spartanburg County were found in and near the large centers of population, and particularly in the cotton-mill villages.
2. Children under the age of 2, adolescents for about five years following puberty and adult males in the active period of life were least frequently affected by pellagra. On the other hand, women from 20 to 44 years of age, old persons of both sexes and children from 2 to 10 years of age were most frequently affected.

PELLAGRA—LAVINDER, FRANCIS, GRIMM, LORENZ

1023

3. No definite connection between occupation and the occurrence of pellagra has been found, although the high pellagra morbidity in the women and children points to the home as the place in which the disease is usually contracted.

4. In the group of incident cases most thoroughly studied, evidence of close association with a preexisting case was disclosed in more than 80 per cent.

5. A house-to-house canvass of the homes of over 5,000 people living in six endemic foci of pellagra failed to disclose any definite relation of the disease to any element of the dietary.

6. In these six villages new cases of pellagra originated almost exclusively in a house in which a pre-existing pellagrin was living, or next door to such a house, suggesting that the disease has spread from old cases as centers.

7. So far as we have observed, pellagra has spread most rapidly in districts where insanitary methods of sewage disposal have been in use.

8. Additional evidence has been obtained to support the conclusion that flies of the genus *Simulium* have nothing to do with pellagra.

9. Animal inoculations and the experimental study of intestinal bacteria have not yielded conclusive results.

10. The studies of the blood have shown a lymphocytosis in most cases, but have not disclosed any constant abnormality characteristic of pellagra.

11. There is no evidence of inheritance of pellagra.

12. The immediate results of hygienic and dietetic treatment in adults have been good, but after returning to former conditions of environment, most of the cases recur. In children, prognosis is very much favorable.

Work was accordingly started in August, 1913, at the laboratory of the United States Public Health Service, Savannah, Ga., and is still in progress at that place.

At the present time we desire simply to make a brief progress report of this work, reserving full details for the report on the completed work.

INOCULATION OF PELLAGROUS TISSUES

1. The brain, spinal cord and their membranes were removed at six necropsies, ground in a meat grinder, mixed with an equal volume of normal saline solution and allowed to extract in the ice-box for periods varying between one hour and eighteen hours. The suspension was then allowed to drip through six thick-nesses of gauze without pressure. The gauze filtrate was either injected into animals without further treatment or injected after filtration through a Berkefeld filter. The gauze filtrate was injected intracerebrally, intravenously and subcutaneously into each of two rhesus monkeys; intraspinally and intraperitoneally into 12; intraspinally and intramuscularly into 2; intracerebrally and intraperitoneally into 2; intracerebrally and intraperitoneally into 2. The Berkefeld filtrate was injected intraspinally into 4.

2. The buccal thoracic and abdominal contents, except intestines, including tongue, salivary glands, tonsils, esophagus, lungs, heart, diaphragm, stomach, liver, spleen, kidneys, omentum and mesentery were removed at one necropsy and all ground in a meat grinder, a portion of which was treated with saline solution and allowed to stand in the ice-box four hours, after which it was squeezed through gauze. A portion of the gauze filtrate was injected intravenously and subcutaneously into each of seven rhesus monkeys. Another portion of the gauze filtrate, after being passed through a Berkefeld filter, was injected intravenously into three.

3. The intestines and fecal contents were removed at seven necropsies, ground in a meat grinder, a portion of which was extracted with saline solution and squeezed through gauze. A portion of the gauze filtrate was injected intravenously and subcutaneously into 7 rhesus monkeys and 1 Java monkey. Another portion, after being passed through a Berkefeld filter, was injected intracerebrally, intravenously and subcutaneously into 1 baboon; intravenously and subcutaneously into each of 10 rhesus monkeys.

4. Skin from five necropsies was ground in a meat grinder, treated with saline solution, squeezed through gauze and a portion of the gauze filtrate injected intracerebrally, intravenously and subcutaneously into 1 rhesus monkey; intravenously and subcutaneously into 1 Java monkey; intravenously and subcutaneously into 3 rhesus monkeys. A Berkefeld filtrate was injected intracerebrally, intravenously and subcutaneously into each of 2 rhesus monkeys.

INOCULATION OF PELLAGROUS FLUIDS AND EXCRETA

1. Blood was drawn from seven pellagrins, and after being either defibrinated or citrated was injected intravenously and intraperitoneally into each of four rhesus monkeys; intravenously into one and intraperitoneally into one.

ATTEMPTS TO TRANSMIT PELLAGRA TO MONKEYS

C. H. LAVINDER, M.D.
Surgeons, U. S. Public Health Service
R. M. GRIMM, M.D.
Asst. Surgeon, U. S. Public Health Service

AND
W. F. LORENZ, M.D.
Director Wisconsin Psychopathic Institute
MENDOTA, WIS.

Attempts to test the infectivity of pellagra by inoculation in the monkey were made by Anderson and Goldberger¹ in the summer of 1910. Their results were negative. Lavinder² repeated and extended these experiments with similar negative results. Singer, MacNeal and Rooks³ likewise failed to infect rhesus monkeys. A year ago Harris⁴ reported the production of pellagra in the rhesus monkey by the inoculation of a Berkefeld filtrate derived from human

4. Harris: The Experimental Production of Pellagra in the Monkey, etc., The Journal A. M. A., June 21, 1913, p. 1948.

2. *Pericardial fluid* collected at one necropsy was injected without filtration, intravenously into two rhesus monkeys and after Berkefeld filtration was injected intraspinaly into each of two.

3. *Urine* from four pellagrins, each of which showed a marked indican reaction, was injected intravenously after Berkefeld filtration into five rhesus monkeys, each receiving between 90 and 155 c.c.

4. *Feces* from one pellagrin after Berkefeld filtration was injected intravenously (15 c.c.) into one baboon.

5. *Cerebrospinal fluid* collected at three necropsies was injected, without filtration, intracerebrally and intravenously into 1 rhesus monkey and intraspinaly into 5. Cerebrospinal fluid collected at 2 necropsies was, after Berkefeld filtration, injected intraspinaly into each of 10 rhesus monkeys. Cerebrospinal fluid collected during life from 19 pellagrins and not filtered was injected intraspinaly into 19 rhesus monkeys.

FEEDING OF PELLAGROUS MATERIAL AND SPOILED CORN MEAL

1. *Sputum* from ten pellagrins collected fresh each day was fed by stomach-tube to five rhesus monkeys, each receiving 100 c.c. daily and receiving a total of 3,640 c.c., 1,658 c.c., 2,140 c.c., 1,635 c.c. and 915 c.c., respectively.

2. *Feces* collected fresh each day from two pellagrins with diarrhea was mixed with spoiled corn meal and fed by tube into the empty stomachs of eight rhesus monkeys, each animal receiving 100 c.c. daily, 20 gm. of which was meal. The average amount fed to each animal was 1,270 c.c.

3. *The thoracic and abdominal organs and contents* complete from five necropsies were ground in a meat chopper and fed by stomach-tube to sixteen rhesus monkeys and three baboons.

4. *Brain, cord and membranes, buccal thoracic and abdominal organs and contents complete* from one necropsy were ground in a meat chopper and to the mixture was added spoiled corn meal. The entire mass was fed by tube into the stomachs of eighteen rhesus monkeys and one baboon.

ANIMALS USED

The animals experimented on embraced seventy-seven rhesus monkeys, two Java monkeys and three female baboons.

With few exceptions each animal was inoculated by more than one route, with two or more kinds of material, from more than one case and on more than one occasion.

In all, 103 experiments have been made, in which material collected from pellagrins during life or at necropsy was introduced into the stomachs of animals; fifty-two experiments were made in which pellagrous fluids were injected and ninety-six in which extracts, suspensions or emulsions of pellagrous tissue were injected.

The animals have been exposed daily to the direct rays of the sun by being kept in cages in a glass-covered house.

RESULTS

Eight of our animals died after a longer or shorter time following inoculation. In four instances death was plainly due to some cause other than pellagra; in the other four the cause of death was undetermined.

With one exception, the surviving monkeys have so far shown no indications suggesting pellagra.

The exception referred to is as follows:

M. rhesus 98 was injected intraspinaly with 6 c.c. of spinal fluid, April 14, 1914, and again inoculated May 2 intraspinaly with 4 c.c. of spinal fluid drawn from another pellagrin. The first change in this monkey was noted May 4, 1914, at which time the right forearm appeared slightly swollen and looked as if some of the hair was falling out. The following day the left forearm showed a similar condition. Later both forearms became entirely denuded of hair, the skin became roughened and scaly with large cracks in which appeared a slight serous exudate. Over both wrists the superficial skin seemed to be denuded and the condition gave the appearance of superficial ulceration. On the posterior surface of each hand a similar condition was noticed; the knuckles of the fingers were swollen and reddish and presented cracks and broken skin. May 9 the skin was dry and more scaly. The bowel movements were occasionally loose. Later thick crusts on the skin came away, leaving a pale and slightly scaly surface. The monkey is now again in his usual condition.

The interpretation of these manifestations is not clear. They may, on the one hand, be regarded as non-pellagrous and purely accidental, or, on the other, as indicating pellagra. The former possibility cannot be ruled out. With respect to the latter it is evident that the symptoms may have been brought about by either a living organism or by some unorganized element having a toxic quality. As a definite interpretation is not permissible, no inference as to the communicability of the disease can be made.

THE TREATMENT OF PELLAGRA*

CARL VOEGLIN

Professor of Pharmacology, U. S. Public Health Service

WASHINGTON, D. C.

When I attempt to present to you our present knowledge of the treatment of pellagra, it is that I want to speak of this phase of the problem from the point of view of the pharmacologist and biochemist. Pharmacology, together with pathology, is the foundation of all rational treatment of disease by means of drugs. Biochemistry, on the other hand, is the fundamental science which gives us the basis for a clear understanding of the processes involved in nutrition and metabolism. As the preceding speakers have sufficiently emphasized the fact that the cause of pellagra has been attributed by many authors for nearly a century to the use of a particular kind of food, the discussion of the treatment of the disease from this point of view does not seem uninteresting, and it may possibly contribute to elucidate the still obscure etiology.

All physicians who have had much experience in the treatment of pellagrins agree on one point, namely, that in the milder cases the symptoms will almost always disappear in a relatively short time if the patients are kept in a hospital at rest on a liberal mixed diet, with plenty of fresh meat. The difficulty in carrying out this sort of treatment is that many pellagrins are mentally defective and refuse to comply with the orders of the physician unless forced to understand that this is the only way for an improvement in their

* Read before the joint meeting of the Section on Preventive Medicine and the Section on Pharmacology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, June, 1914.

condition. The attending physician must, therefore, use all available psychotherapeutic methods in order to succeed with the dietary treatment. I cannot enter here into a discussion of the adjustments of the diet in cases associated with vomiting, constipation or diarrhea, which require special dietary measures. It may be said, however, that a mild diarrhea should not be treated with a reduction in the quantity of the diet, as it has been found through metabolic studies that the assimilation of the food is unimpaired in this condition. Constipation is favorably influenced by an increase in the fats of the diet, such as olive oil, butter, cod-liver oil, etc., or by the continued administration of small doses of castor oil. It is interesting to note that patients whose symptoms have disappeared on such treatment will again develop symptoms after having been exposed for several months at their home to the same conditions which prevailed before the onset of the first attack. On the other hand, there are cases on record in which, after dismissal from the hospital, the patients remained well for years. Advanced cases of pellagra, and especially the so-called typhoid pellagra, are often unimproved by any available treatment and end fatally in a shorter or longer period of time.

Let us now turn for a moment to the efficacy of drugs in the treatment of this disease. Lombroso and his school advocated the administration of arsenic in the form of Fowler's solution to pellagrins. Lombroso even went so far as to call arsenic the specific for the disease. His extremely optimistic attitude toward this remedy is not shared by many of his compatriots. In this country arsenic also has its adherents. With the introduction of the cacodylates and salvarsan into therapy, it can be easily understood how these arsenicals were also given a trial in pellagra. Some American authors claim to have had good results from such treatment, while others do not believe in the efficacy of the drug. It cannot be denied that arsenic in any form may be beneficial in many cases of pellagra associated with a loss of body weight and malnutrition, when it seems necessary to make use of this metabolic tonic. Sodium chlorid internally was also advocated by Lombroso, especially for the treatment of pellagra in children. Very little can be said, however, in its favor or in behalf of the dozens of other drugs suggested at different times for the treatment of this disease.

In closing this chapter I should like to call your attention to the fraudulent advertising of proprietary pellagra medicines throughout the Southern states. The manufacturers of these preparations usually claim in a sensational manner that these preparations will positively cure pellagra. Some of these mixtures were analyzed¹ at the Hygienic Laboratory and were found to contain such substances as charcoal, iron salts, small quantities of quinin, etc. It is evident that no cure would be affected by such preparations. "These preparations have usually sold at prices that would be exorbitant for remedies of value in the treatment of the disease. When one considers that most pellagra patients are found among people of small means the advantage taken of the sick and unfortunate by the manufacturers of these nostrums appears in its true light."

Another phase of the treatment concerns the well-known relation between pellagrous erythema and

exposure to sunlight. This fact should be a caution to the patient to keep out of bright sunlight as much as possible. Hydrotherapy may be a useful addition to the treatment. Transfer of the patient to a cooler climate seems to be followed by an improvement in the symptoms, provided that the dietary and general hygienic measures are observed. Attention should be called to the fact that pellagra has developed in persons in the northern climates such as Canada, England and our New England States.

Summing up the previous statements it may be said that, owing to the lack of knowledge regarding the etiology of the disease, the treatment is restricted to symptomatic and empirical procedures in which diet and rest figure most prominently.

In conclusion, I should like to offer a few suggestions in regard to the possible explanation of the beneficial effect of a liberal diet on the course of the disease. From a survey of the clinical and pathologic aspects of pellagra, I have arrived at the conclusion that we are dealing with a chronic intoxication. While the agents at work in this intoxication are as yet unknown, I am inclined to believe that toxic substances exist in certain vegetable foods, not necessarily spoiled, which, if consumed by man over a long period of time, may produce an injurious effect on certain organs of the body. This hypothesis does not rule out the possibility that a dietary deficiency, in the sense to be discussed later, may play a rôle in the production and treatment of pellagra. Extensive feeding experiments which I have carried on during the last year with animals, such as mice, rats and a few monkeys, on an exclusive vegetable diet, have shown that these lower animals develop certain gastro-intestinal symptoms, and sometimes die if put on an exclusive diet of corn, carrots, sweet potatoes, oats, etc. Symptoms arise, often within three or four days, which point to the presence of an intoxication in these animals. Death resulted in some cases in a remarkably short time (three to four days). At necropsy constant lesions were found, such as hyperemia and hemorrhage in the gastro-intestinal canal. Sometimes the kidneys, lungs and other organs show a congestion and slightly hemorrhagic condition. Preliminary experiments showed that extracts of these vegetable products, if fed or injected into animals, produced the same symptoms.

In an investigation by Dr. Myers and myself² for the purpose of ascertaining the nature of the toxic substances involved in this intoxication, the fact was revealed that relatively large amounts of soluble aluminum compounds were present in these vegetable products. It is very difficult to decide at present whether these aluminum salts have any injurious effect on man in the quantities taken up with the food. Toxic effects from the administration of aluminum salts to animals have been observed, and even a few cases of aluminum poisoning in man have been found in the literature. In view of the fact that the animals which were fed on an exclusive diet of corn or certain other vegetables always showed on necropsy gastro-intestinal lesions, it would seem that this diet, to say the least, produced a disturbance in the function of these organs.

It is not always permissible to apply directly the results obtained through animal experimentation to clinical conditions, but these experiments seem to fur-

1. Public Health Reports, 1914.

2. Public Health Reports, 1914.

nish at least the basis for an understanding of the effect of a change in diet on the course of pellagra. By substituting for part of the vegetable food, animal foodstuffs, such as meat, eggs, etc., the absolute amount of vegetable products consumed will be reduced considerably. Hence we probably also reduce the possibility of an injurious action of the vegetable food on the body, particularly the irritant action on the gastro-intestinal canal. Meat is known to be easily digested by pellagrins, leaving practically no unassimilated residue in the intestine. Meat, furthermore, satisfies the appetite in much smaller quantities than does the voluminous vegetable diet with its relatively large amount of undigested cellulose.

Besides the differences in digestibility and food value in the old sense, we have also to consider the specific effect of each constituent of the diet apart from the question of calories, protein, carbohydrates and fats. In the past all of our attention concerning the nutrition of man was devoted mainly to a study of the heat value of food and the proportion of protein, carbohydrate and fat to each other in a given diet. It is only in the last few years that we have realized that there may occur very important differences in the composition of the individual proteins. The work of Fischer, Abderhalden, Mendel and Osborne has shown the great variation in the composition of protein in regard to its content of the various amino-acids. Feeding experiments with the isolated proteins brought to light the fact that, although all proteins are absorbed and assimilated to about the same degree, yet certain proteins lack or are deficient in certain amino-acids essential for growth and maintenance. Most of the proteins derived from animal sources, with the exception of gelatin, seem to be more suitable for human nutrition, as they contain all the necessary components in the right proportion. Some of the vegetable proteins, on the other hand, seem to be deficient in this respect. It can hardly be denied that the majority of the persons who contract pellagra have lived for years on a mainly vegetable diet. In this way a deficiency in nutrition may take place, but it will require considerable further research to establish the fact that food composed of certain vegetable products is insufficient for the demands of the body.

Quite recently another field in nutrition was opened up through the discovery of the presence of small quantities of new substances occurring in foods which seem to be essential for the maintenance of health. These substances are termed vitamins by Funk. They occur in animal as well as vegetable food in varying amounts. Certain foodstuffs, as polished rice, are extremely poor in vitamins; others, as meats, are relatively rich in these substances. The hypothesis has been advanced by Funk that pellagra is a disease due to the lack of some vitamin in food, analogous to the production of beriberi through the more or less exclusive consumption of polished rice. So far no experimental or clinical proofs have been advanced to support this hypothesis.

Summing up these remarks, we see that our modern conceptions of nutrition and metabolism throw some light on the beneficial effect of a liberal mixed diet on the course of pellagra. In conclusion, I should like to say just a few words in regard to the question as to how these same conceptions may help to explain the etiology. It is probably more than a mere coincidence that the population of that part of the world in which

pellagra is endemic lives on a mainly vegetable diet. Economic conditions seem to influence in a general way the diet of people. A vegetable diet is as a rule less expensive, and persons in poor circumstances limit the consumption of the costly meats and other animal food to a minimum. In this connection I should like to call your attention to the fact that pellagra appeared in France soon after the reign of the first Napoleon, a period which was followed by extreme poverty in the country. France recovered from this economic depression in the latter part of the nineteenth century. With this change in economic conditions, partly brought about through the introduction of the more profitable wine industry, pellagra decreased to such an extent that the disease is now very rare in that country. It is impossible to say at present that the food as such is the only factor in the production of pellagra, but even some of the adherents of the infectious theory do not deny that the one-sided diet may be one of the contributing factors in the production of this disease.

The recent advances in the field of nutrition suggest new avenues of approach to the solution of this difficult problem. One will have to consider very seriously:

1. A deficiency or absence of certain vitamins in the diet.
2. The toxic effect of some substances, as aluminum, which occur in certain vegetable food.³
3. A deficiency of the diet in certain amino-acids.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. SILER, GARRISON AND MACNEAL; DRS. LAVINDER, FRANCIS, GRIMM AND LORENZ, AND DR. VOEGTLIN

DR. MARCUS HAASE, Memphis, Tenn.: Some three or four years ago the State Board of Health of Tennessee declared pellagra a transmissible disease, required the physician to report it and the case to be isolated. It can be easily seen how utterly impracticable it would be to carry out any such order, as the cases would have to be under constant official surveillance. The staff of the city hospital in Memphis fought that for about a year and succeeded in having the restriction removed so far as the city of Memphis was concerned. We then began taking in pellagrins constantly; and, with very few exceptions, in the past three years there has not been a month that there has not been one or more pellagrins in the city hospital. During that time, in which we have cared for some 150 or more cases, no case of pellagra has occurred in any inmate of the hospital, or among those constantly employed there, in number over 70. No case has occurred among the patients in the hospital that we could trace to any former case of pellagra. The disease is increasing in our district at an alarming rate. While the death-rate of pellagrins has decreased, the morbidity rate has decidedly increased in the past three years.

DR. R. Q. LILLARD, Nashville, Tenn.: As executive officer of the State Board of Health of Tennessee, I want to correct Dr. Haase on one proposition. The question of the quarantine of pellagrins was brought to the attention of the present State Board of Health, a resolution requiring the quarantining of the disease having been passed by the former

3. The possible relation between aluminum and pellagra was also discussed in a recent monograph by Alessandrini and Scala (*Contributo nuovo alla etiologia e patogenesi della Pellagra*, Roma, 1914), which the author received at the time of proof-reading. These investigators claim that colloidal silica contained in drinking water is one of the most important etiologic factors, in as much as they succeeded in producing lesions resembling pellagra in animals fed on water containing colloidal silica. Colloidal aluminum hydroxid or a mixture of colloidal silica and alumina produced the same results. In view of the fact, silica and alumina produced the same results. In view of the fact, first discovered by us, that aluminum occurs in certain vegetable food in relatively large amounts, the work of the Italian authors furnishes additional evidence that aluminum occupies a prominent position in the etiology of pellagra.

board. I immediately asked the state bacteriologist if he was ready to classify it as a communicable or contagious disease. He said he was not; and the board of health immediately revoked their resolution.

DR. W. C. BROWNSON, Asheville, N. C.: I am fairly familiar with the work of the Thompson-McFadden Pellagra Commission. I know something of how thorough the work has been. While the etiology is still in doubt, it is probable that the disease has some gastro-intestinal cause, and that it may occur from faulty disposition of sewage would seem exceedingly probable. I had no idea that experiments on such an extensive scale had recently been made with monkeys, and after such exhaustive experiments, the fact that most of the monkeys are still living and well, and show no positive signs of the disease would seem to eliminate almost entirely the question of the communicability of the disease from one person to another. It is evident enough that there is no specific for the treatment of pellagra, and the probability is that no medicine does much good. I have had no reason to modify my opinion, expressed long ago, that pellagra should be treated much as we treat tuberculosis, by rest, an abundant nourishing diet, and change of climate when possible. Sodium cacodylate is the most popular medicine at present. Salvarsan has been recommended as a specific, but to me, there is no evidence that it has done good. Sodium cacodylate may do good at times. Two years ago I used it in a number of cases. Most of them seemed to do well. Last year not a single patient with whom I used it seemed to derive any benefit whatever.

DR. W. T. SHELL, Corsicana, Texas: I concur with Dr. Siler that pellagra is a gastro-intestinal trouble. I have used the arsenic preparations, sodium cacodylate and salvarsan in quite a number of cases, but find that better results may be obtained from the gastro-intestinal treatment.

DR. JOHN L. JELKS, Memphis, Tenn.: As the original exponent of the intestinal-infection theory as to the etiology of pellagra, I wish to relate a few things I have observed. Some years ago, I referred to the ameba, which I believed then to be the cause, and in the first part of April, 1910, I presented a pellagrin before the Tennessee State Medical Association, who was suffering from chronic amebiasis. I now have a case, apparently of pellagra, presenting pellagrous skin lesions on elbows and legs. This patient I know has had amebiasis twelve years. I saw him, and made the diagnosis twelve years ago. This man is being nursed by a woman who was brought to me from Mississippi, and was treated by me for pellagra. I performed an appendicocostomy on her, which enabled me to treat the condition rationally, as I view it. That woman is well. She is a little nervous yet, but any one would pronounce her entirely well. The man she is nursing, as in the case of pellagra, exhibits a profound toxemia, and is quite tender along the cervical region. Pellagra represents the results of a profound toxic effect on the blood and nervous system, and the ameba, I believe, is often the cause. I have observed a great increase in the bacillary contents of the intestine, and in one case, reported in my chapter on Dysentery in Hirschman's book, I observed in the *Ameba histolytica*, blunt non-motile bacilli, which were somewhat larger at one end. This was in a case of amebic dysentery of long standing, and a well-defined case of pellagra. The first case reported by me, as stated, was April 12, 1910. A year earlier, however, I reported cases of the skin manifestations of amebiasis. A negress, the body-servant of the nurse referred to, has pellagra. The nurse did not contract the disease direct from the servant, but it is probable that both contracted the disease from polluted water or infected vegetables. In our part of the country, the vegetable gardens are being infected, and infected vegetables are going to prove a greater menace to the health of our people than we realize at present. I cannot ascribe an etiologic significance either to corn or to the *Simulium reptaens*. I am rather inclined to the bacillary toxic origin, though the ameba may be the host. Salvarsan never cured a patient. The results obtained by its use were from the salt solution, which washed the toxic blood and diluted

the toxins. The same results would have been obtained from salt solutions. The treatment must be begun in the early stages, before irreparable damage has been done to the central nervous system, for, thereafter, there is no cure.

DR. ROBERT WILSON, JR., Charleston, S. C.: In Charleston we gave up, some time ago, the theory advanced by Dr. Sambon that the possible carrier is a *Simulium*, for while cases of pellagra are fairly numerous the simulum is not found. Several pellagrins have come under my observation who were born in Charleston, and have never been out of the city. On Johns Island, a sea island near the city, which, if I am not mistaken, is the one alluded to by Dr. Siler, pellagra has existed for a number of years. This island is one of the low sandy islands of the coastal region, and there are no running streams on it, and no *Simulidac*. It is my impression, although I am not able to give statistics off hand, that with us pellagra is much more common in the negro than it seems to be in the upper part of the state where the Thompson-McFadden Commission have been working. I was much interested in hearing Dr. Siler's conclusion with regard to the possible influence of soil pollution on the prevalence of pellagra. In Charleston it is only recently that we have introduced a water-carriage system of sewage disposal, old-fashioned surface privies having been in use for a great many years, with consequent soil pollution. This may possibly explain the relatively large amount of pellagra which occurs in Charleston. It will be exceedingly interesting to note if the introduction of the new sewage disposal system and the destruction of the surface privies will be followed by a diminution in the prevalence of pellagra.

DR. WARD J. MACNEAL, New York: In 1910 the Illinois Pellagra Commission undertook to transmit pellagra to monkeys, using *Macacus rhesus*. Something over 100 monkeys were used. Many of the animals were injected with blood; some with cerebrospinal fluid; others with tissues taken at necropsy. Some rather curious and interesting skin lesions developed in a few of these animals, but nothing which we could recognize as typical of pellagra. Many of the monkeys lived two years after inoculation. The Thompson-McFadden Pellagra Commission has now used about 125 monkeys in the work which was reported here. Some of these animals have lived considerably more than two years after being inoculated and, so far, we have been unable to see in any of them, anything which we could regard as a reliable sign of pellagra. The skin lesions which most closely resembled those seen in human pellagra occurred in one of the animals that we saved as a control. It seems to me very important that a considerable number of animals should be kept as controls in all such experiments. It is exceedingly difficult to make a diagnosis of pellagra in a monkey satisfactory to everybody. I would like to ask Dr. Francis about the time interval between inoculation and the appearance of the lesions. It seems rather important also to know how long after the material was collected it was introduced into the monkeys. This is particularly important in the one instance in which the suggestive skin lesions were obtained. The details with regard to that one animal would be of interest. Something may be said concerning the prognosis in pellagra. One might get the idea from Dr. Voegtlin's paper that typhoid pellagra is invariably fatal. One case of this type occurred in the Illinois State Hospital at Kankakee. The patient was in a typhoid state for a period of three or four days, yet she recovered from the attack and has remained free from recurrence for four years. In another patient, observed in 1912, occurred one of the severest attacks of pellagra that I ever saw. The patient was in a typhoid state for a week, yet she recovered from that attack and has since had no recurrence. There is some indication, therefore, that these severe attacks of pellagra are not necessarily fatal. Accurate prognosis is exceedingly difficult in any of these cases. Dr. Voegtlin stated that pellagra could not be found except in people who had lived for many years on a vegetable diet. I don't know on what observations that statement has been based; but it seems to me there is good indication that pellagra can be recognized in some

persons, particularly in children 2 or 3 years old, who have not lived very long on a vegetable diet; who have, in fact, lived on a diet consisting largely of milk. It seems to me that that statement ought not to pass unchallenged.

DR. CLAUDE SMITH, Atlanta, Ga.: If this case had been referred to Dr. Siler, what would the commission's reply have been, and in the light of their present knowledge, what would they advise with regard to the handling of pellagra cases? In addition to the question which Dr. MacNeal has asked as to the time of inoculation, will Dr. Francis state the type of inoculations made on this monkey, and the length of time which had elapsed when the lesions appeared?

DR. J. F. SILER, New York: Dr. Smith has asked a difficult question; one which it is not possible to answer definitely. It is our opinion that pellagra is an infectious disease. Our epidemiologic and laboratory studies have not, so far, given us any definite clue as to the probable nature of the hypothetical virus. We advise in these cases improvements in sanitary conditions. The things which we consider most important are personal cleanliness, thorough screening of dwelling-houses and improvements in methods of disposal of excreta. We stress the importance of having fly-proof privies and screened dwellings, not only as a possible protection against pellagra but also as preventive measures for such common diseases as typhoid, dysentery, hookworm, summer diarrheas, malaria, etc. Dr. Haase spoke of the fact that pellagra never spreads in hospitals. This is interesting and difficult to explain. I studied pellagra at the Peoria State Hospital when the disease existed there in epidemic form. There were about 175 cases or 8 per cent. of the inmates. None of the nurses or doctors contracted the disease. This institution had, during the same period of time, about 75 inmates showing active symptoms of tuberculosis and also an epidemic of amebic dysentery. None of the nurses or doctors, so far as I could learn, showed any evidence of having contracted tuberculosis from these patients, nor did any of them have dysentery. It will, I think, be admitted that the character and degree of association between nurse and pellagra patients in hospitals and the environmental conditions surrounding this association, are quite different from those existing in the homes of the element of the population in which pellagra is found most frequently. As a matter of fact, I know that a number of physicians in the Southern States have had pellagra and I have had reports of pellagra in five nurses. These are merely unconfirmed reports, however, which we hope to investigate fully. In our investigations in the South, the entomologists from the Bureau of Entomology who are collaborating with us have found the bedbugs are practically universal in the element of the population most frequently affected by pellagra. This applies particularly to mill communities where pellagra is most prevalent. One striking feature of the epidemiology of pellagra is that males between 20 and 45 years of age seldom contract it. In this age period there are about nine females to every male pellagrin. It cannot be said that adult males are relatively immune to the bites of bedbugs.

DR. JOHN RITTER, Chicago: Is it considered a fact that the bedbug is a carrier of pellagra infection?

DR. EDWARD FRANCIS, Washington, D. C.: Dr. MacNeal has asked for some specific data with regard to Rhesus 98, the monkey which showed the skin eruption. This monkey was injected intraspinally with 6 c.c. of spinal fluid, April 14, 1914, and was again inoculated May 2, intraspinally, with 4 c.c. of spinal fluid drawn from another patient. Both pellagrins were insane.

DR. CARL VOEGTLIN, Washington, D. C.: The Thompson-McFadden Pellagra Commission asserts that pellagra is an infectious disease. The proofs advanced so far are only indirect and, therefore, not conclusive. The methods used by the Commission for the study of the relation of food to pellagra are defective inasmuch as they do not take into full consideration the quantity and quality of each food in the diet. It is a great mistake to make such superficial dietary studies, which often lead to false conclusions, a fact well illustrated in the history of the etiology of beriberi. Not every person

who consumes polished rice contracts beriberi, because the production of this disease depends on the quantity of polished rice consumed as well as the quantity and quality of the other foods contained in a particular diet. It would be absolutely wrong to say that, because many people eat polished rice daily together with other food without getting beriberi, rice did not have anything to do with beriberi. This fact was well brought out in the feeding experiments in the Japanese navy. As soon as part of the polished rice was replaced by certain other food, beriberi began to disappear. Yet the Japanese sailors still had rice in their daily ration. The dietary studies carried out by the experiment stations of the Department of Agriculture in various sections of the Southern States are of much value, as they determine the amount of each food consumed by the various families. These studies plainly show that the vegetable foods preponderate greatly over the animal food in the diet commonly used in the South. Sometimes the diet consists entirely, as you may know, of corn and fat pork.

I admit that the question of the appearance of pellagra in young children in its relation to food is a difficult problem to solve. I think, however, that there exists a possibility of explaining it on the assumption that toxic substances are consumed by the mother which are excreted with the milk and cause an intoxication of the infant. Another possibility is the absence of certain substances—vitamins—in the milk. It is well known that nursing mothers who have beriberi will often give the disease to their infants. As soon as the infants receive normal milk the symptoms will disappear. There exists, therefore, an intimate relation between the composition of the milk of the mother and the health of the infant. If the infant is fed on cow's milk we may deal with a similar proposition. Cows eat exclusively vegetable food, and it is quite possible that certain toxic substances consumed will go over into the milk. We found, for instance, that cow's milk contains considerable quantities of aluminum. Of course I admit that this is all indirect evidence and does not prove definitely that pellagra is a disease due to a dietary deficiency or to the presence of toxic substances in the diet. On the other hand, I can say that just as much weight of argument is on the side of the nutrition theory as on the side of the infection theory.

IMMUNITY IN TUBERCULOSIS

FURTHER EXPERIMENTS*

GERALD B. WEBB, M.D.

AND

GEORGE BURTON GILBERT, M.D.

COLORADO SPRINGS, COLO.

In 1911, experiments were reported¹ on twelve monkeys. The subsequent history of those not killed at that time follows:

MONKEY 1.—Control. Jan. 19, 1912. The monkey had not become spontaneously infected since its purchase, June 8, 1910.

Oct. 14, 1912: Intradermal tuberculin test 0.1 mg. O. T. Result negative.

Dec. 1, 1912: Animal has refused to eat for three days. Found dead. Necropsy, no trace of tuberculosis anywhere.

MONKEY 2.—Received 25 virulent human tubercle bacilli by subcutaneous injection. June 9, 1910, thirty-five bacilli of this culture had infected a guinea-pig (Barber culture). June 7, 1911, killed. No evidence of tubercle anywhere. Lymph-nodes from various parts ground up and injected into guinea-pig without producing infection.

* This work was assisted by a grant from the Committee on Scientific Research of the American Medical Association.

* Read before the Section on Pathology and Physiology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

1. Webb, G. B., and Williams, W. W.: Immunity in Tuberculosis, *THE JOURNAL A. M. A.*, Oct. 28, 1911, p. 1431.

MONKEY 3.—Received 100 virulent human tubercle bacilli by subcutaneous injection, of same culture, June 8, 1910.

Sept. 6, 1911: Conditions resembling elephantiasis had developed. Animal killed. Lower half of vulva, buttocks, tail, legs, showed dense infiltration of skin about $\frac{1}{2}$ inch in thickness. The swollen parts were soft but firm. Edematous, not reddened. All organs normal. No signs of tuberculosis anywhere. Pieces of swollen area, lymph-nodes from various parts ground up and injected into guinea-pig without infection resulting.

MONKEY 4.—Received 200 human tubercle bacilli of same culture by subcutaneous injection, June 8, 1910.

lesions in liver. Scattered tubercles in lungs. This monkey was evidently infected on arrival or shortly after. The positive intradermal reaction was the first we had experienced in any monkey and the decisiveness convinced us that those reported in our former papers were probably not positive.

Through the courtesy of Dr. Lawrason Brown of Saranac, a culture (Brown C₁) was received from which Dr. Brown had been able to infect a guinea-pig with 20 bacilli. We wished to ascertain how many bacilli of this culture would, inoculated subcutaneously, infect a monkey.

Preliminary experiments were made on guinea-pigs with results mentioned below.

Chart 3.—Percentage of mononuclears, Monkey 14.

GUINEA-PIG 2.—Twenty-five bacilli inoculated into right nipple area.

GUINEA-PIG 3.—Nov. 11, 1912: Several thousand bacilli inoculated into right nipple area.

GUINEA-PIG 4.—Twenty-five bacilli inoculated into right nipple area.

GUINEA-PIG 5.—Fifty bacilli inoculated into right nipple area.

GUINEA-PIG 6.—Fifty bacilli inoculated into right nipple area.

GUINEA-PIG 7.—One hundred bacilli inoculated into right nipple area.

GUINEA-PIG 8.—Ten bacilli inoculated into right nipple area. All pigs became definitely infected and tuberculosis was confirmed by necropsies.

This culture, from which only ten bacilli could cause infection, was evidently more virulent than any we had before employed.

Inoculations were made into guinea-pigs in increasing doses as the records indicate (Tables 1 and 2), but each pig finally developed tuberculosis.

TABLE 1.—INOCULATIONS INTO GUINEA-PIG 6

Date	Tubercle Bacilli	Date	Tubercle Bacilli
1/ 9/13	2	2/ 3/13	14
1/13/13	4	2/ 6/13	16
1/16/13	6	2/10/13	20
1/20/13	8	2/13/13	25
1/23/13	9	2/17/13	30
1/27/13	10	2/20/13	35
1/30/13	12	2/24/13	40

Feb. 27, 1913: Pig has local lump at inner side of left nipple.

TABLE 2.—INOCULATIONS INTO GUINEA-PIGS 30, 31 AND 32

Date	Tubercle Bacilli	Date	Tubercle Bacilli
5/19/13	R 2	6/23/13	L 12
5/26/13	R 4	6/30/13	L 14
6/ 2/13	L 6	7/ 7/13	R 16
6/ 9/13	L 8	7/10/13	R 20
6/16/13	L 10	7/21/13	R 20

Injections were made into right and left nipple areas according to designation R or L.

July 21, 1913: Probable infection of groin glands on left side.

Sept. 3, 1913: Definite infection of groin glands on left side.

MONKEY 15.—Jan. 20, 1913: Three hundred bacilli, Culture Brown C₁, inoculated just below left nipple.

March 4, 1913: Large local lesion at site of inoculation. Enlarged gland in left axilla. Intradermal tuberculin test ++ (positive).

March 6, 1913: Killed. Local lesion and infected axillary gland. Otherwise no evidence of tuberculosis.

MONKEY 16.—July 1, 1912: Broken leg; discarded. Necropsy negative.

MONKEY 17.—Oct. 31, 1912: Prolapsed bowel, discarded. Necropsy: lobar pneumonia.

MONKEY 18.—Jan. 20, 1913: Four hundred bacilli, Culture Brown C₁, inoculated just below left nipple.

March 4, 1913: Large local lesion. Enlarged hard gland in left axilla. Intradermal tuberculin test ++ (positive).

March 24, 1913: Sent to Dr. John F. Anderson, Public Health Service, Washington, D. C. This monkey was ideally infected for an attempt at cure by the Friedmann remedy, but died after a few months.

MONKEY 19.—March 31, 1913: Sixty bacilli, Culture Brown C₁, injected near right nipple.

June 26, 1913: No local lesion or enlarged glands.

Nov. 12, 1913: Subcutaneous tuberculin test (Chart 5) negative.

June 3, 1914: Killed. Necropsy completely negative.

MONKEY 20.—March 31, 1913: Twenty-five bacilli, Culture Brown C₁, inoculated near right nipple.

May 7, 1913: No local lesion.

May 29, 1913: No local lesion or glands enlarged.

Nov. 13, 1913: Tuberculin reaction (subcutaneous test). Notice (see Chart 6) interference with night drop. Probably positive.

Dec. 10, 1913: Found dead. Necropsy negative except for a pus-sack in lesser peritoneal cavity. No tubercle bacilli could be found on staining this pus. No enlarged bronchial glands.

MONKEY 21.—Nov. 12, 1913: Subcutaneous tuberculin test (Chart 7) negative.

Chart 4.—Temperature chart of Monkey 13.

Jan. 8, 1914: A burn made above left ankle which produced a linear scar.

Feb. 26, 1914: Three hundred bacilli (Culture Brown C₁) injected into scar. The site of inoculation bled and the blood was reinjected into two other places in scar.

MONKEY 23.—Nov. 12, 1913: Subcutaneous tuberculin test (Chart 9) negative.

Feb. 26, 1914: Three hundred bacilli (Culture Brown C₁) injected into left leg.

Blood Examinations:

MONKEY 21.—Feb. 27, 1914: Platelets 468,000. Whites 12,600. Lymphocytes 64.5 per cent.

MONKEY 23.—Feb. 27, 1914: Platelets 400,000. Whites 11,000. Lymphocytes 54.5 per cent.

MONKEY 21.—March 10, 1914: Platelets 532,000. Whites 16,600. Lymphocytes 64.5 per cent.

MONKEY 23.—March 10, 1914: Platelets 416,000. Whites 17,060. Lymphocytes 57 per cent.

MONKEY 21.—March 12, 1914: Platelets 516,000.

MONKEY 23.—March 12, 1914: Platelets 384,000.

MONKEY 21.—March 25, 1914: Platelets 542,000. Lymphocytes 72 per cent.

MONKEY 23.—March 23, 1914: Platelets 504,000. Lymphocytes 60 per cent.

MONKEY 23.—April 1, 1914: Has a local lump. No enlarged glands.

April 2, 1914: This lump removed under ether.

April 3, 1914: Good healing. No glands in either monkey.

MONKEY 21.—Platelets 596,000.

MONKEY 23.—Platelets 440,000.

April 28, 1914: Both monkeys killed. Necropsy:

MONKEY 21.—Several tuberculous nodules in liver, also liver abscess. Tuberculous glands in peritoneum. The scar had become ulcerated and had bled easily. No inguinal glands were infected.

MONKEY 23.—Necropsy completely negative.

MONKEY 22.—March 31, 1913: Ten bacilli (Culture Brown C.) injected just below right nipple.

May 7, 1913: No local lesion.

July 29, 1913: No local lesion or enlarged gland.

Nov. 12, 1913: Subcutaneous tuberculin test (Chart 8) negative.

Aug. 3, 1914: Killed. Necropsy negative.

MONKEY 24.—March 31, 1913: One hundred bacilli (Culture Brown C.) injected near right nipple.

May 28, 1913: Local lesion, hard lump. Enlarged gland in right axilla.

May 29, 1913: Under ether local lesion and enlarged gland and axillary gland completely removed.

June 26, 1913: Complete healing, no evidence of enlarged glands or return of lesion.

Chart 5.—Temperature chart of Monkey 19.

Sept. 10, 1913: Killed. Portions of left eye and left side of neck swollen. Extensive tuberculosis of lungs, spleen and bronchial glands. Glands over sternum and in neck all purulent. Few tubercles in liver. No local glands in right axilla.

GUINEA-PIG 55.—Dec. 29, 1913: Given 200 bacilli (Lil culture) at nipple area.

Jan. 18, 1914: Local lesion and enlarged inguinal gland.

Jan. 20, 1914: Nipple, local lesion and inguinal glands removed and entire groin cleaned out down to muscles under ether.

March 5, 1914: Groin entirely healed.

April 11, 1914: Killed. Extensive tuberculosis of liver, spleen and lungs.

The following attempt to treat tuberculous guinea-pigs with inoculations of living tubercle bacilli is of interest:

Dec. 19, 1912: Guinea-Pigs 13, 15, 16 and 17, weighing about 500 gm., were each given 25 bacilli of Culture Brown C₁ in right nipple area.

Jan. 13, 1913: Each pig has slightly enlarged and hard right inguinal gland. Pigs 16 and 17 were used as controls. Pigs 13 and 15 were given inoculations of live tubercle bacilli from the same culture as that producing the infection. These

Chart 6.—Temperature chart of Monkey 20.

inoculations were given in the left nipple area, the numbers given being slowly increased from 1 to 60 during a period of twelve weeks.²

Table 3 gives the numbers given and the dates.

Date	Tubercle Guinea-Pig 15	Bacilli Guinea-Pig 13	Date	Tubercle Guinea-Pig 15	Bacilli Guinea-Pig 13
1/9/13	2	1	2/10/13	20	14
1/13/13	4	3	2/13/13	25	16
1/16/13	6	3	2/17/13	30	20
1/20/13	8	5	2/20/13	35	25
1/23/13	9	6	2/24/13	40	30
1/27/13	10	7	3/3/13	45	35
1/30/13	12	8	3/10/13	50	40
2/3/13	14	10	3/27/13	50	40
2/6/13	16	12	4/3/13	60	50

April 21, 1913: Guinea-Pig 13 had discharging sinus in right nipple area. Killed. Large inguinal glands on right side. Large local lesion. Few tubercles in spleen. Otherwise negative.

May 8, 1913: Guinea-Pigs 15 and 16 were killed. Each had dry ulcer and large local lesion. Right inguinal glands were of equal size. Guinea-pig 16 showed no other tuberculous lesions. Guinea-Pig 15 had a few tubercles in spleen and very minute enlarged bronchial glands.

Nov. 22, 1913: Guinea-Pig 17 killed. Local lesion and right inguinal glands same as others. No other tuberculous lesions. This experiment certainly failed to show any favorable action due to the treatment given. Two pigs in the same series, Guinea-Pigs 14 and 18, treated with tuberculin showed much more extensive and widespread tuberculosis.

It has probably been taken for granted that virulent cultures are all of equal potency. By means of the Barber technic of isolating definite small numbers it may be shown that this is not the case.

2. These experiments also prove that a tuberculous guinea-pig is immune to subsequent small lethal doses inoculated subcutaneously. "Römer, and following him Tomarkin, were able to show a sustained resistance of moderately tuberculous guinea-pigs toward a fresh cutaneous inoculation. A similar immunity toward a subcutaneous dose, so far as I know, has not yet been demonstrated."—Smith, Theobald: An Attempt to Interpret Present-Day Uses of Vaccines, THE JOURNAL A. M. A., May 24, 1913, p. 1591.

Table 4 gives a list of certain cultures and the smallest number so far found capable of producing progressive and fatal tuberculosis in adult guinea-pigs.

TABLE 4.—POTENCY OF FATAL CULTURES

Cultures	Minimum Lethal Number
1. B	120 bacilli
2. Barber	35 bacilli
3. Brown C ₁	10 bacilli
4. Lil	35 bacilli
5. Bd	10 bacilli
6. Ht	50 bacilli
7. Rgis	10 bacilli

Chart 7.—Temperature chart of Monkey 21.

Culture 1 has already been described.³ Three years later this culture from which 120 bacilli had infected a pig, had so decreased in virulence that 100,000 failed repeatedly to infect a guinea-pig.

Culture 2 has also been described.⁴

Culture 3 was isolated in Saranac Lake from the sputum of an advanced consumptive.

Cultures 4, 5, 6 and 7 were grown from the sputum of advanced active cases of pulmonary tuberculosis by means of the antiformin method grown on Dorset's egg-medium and tested within a few months after first obtained.

The following experiment was undertaken to compare the infection produced by the same dosage in two very young guinea-pigs, A and B, a pregnant female pig, C, a nursing female pig, D, and a normal male pig, E, weighing, respectively, 163, 128, 709, 591, and 573 gm.:

- Jan. 13, 1914: Each pig received 60 bacilli, Culture "Lil."
- March 29, 1914: A died of extensive tuberculosis.
- April 12, 1914: B died of extensive tuberculosis. C, D and E in good health.
- June 8, 1914: C, D and E killed. Necropsies showed: C, very extensive tuberculosis; D, no evidence of tuberculosis; E, moderate amount of tuberculosis.

It is of course possible that D failed to receive the bacilli at the time of inoculation. The disease made more rapid progress in the pregnant female than in the normal male and was of a galloping type in the tiny pigs.

Very young guinea-pigs would seem to be much more susceptible to infection by a definite number of bacilli than the older pigs used.

The following experiments on calves are of interest as they indicate the small number of virulent bovine bacilli which may cause infection, and also that a calf can apparently overcome a mild infection.

Table 5 shows the approximate number of virulent bovine bacilli given to the different calves on the various dates.

TABLE 5.—INOCULATIONS INTO CALVES

Calf No.	Age, Weeks	9/20/11	10/4/11	11/15/11	12/1/11	12/11/11	1/20/12	2/13/12
1.	3	50	...	...	5,000	100,000	1,000,000	50 million
2.	13	50	250	500	5,000	...	500,000	5 million
3.	3	50	250	500	5,000	100,000	1,000,000	50 million
4.	3	...	...	...	500	100,000	1,000,000	50 million
5.	3	...	...	...	500	5,000	500,000	5 million
6.	3	...	...	...	500	5,000	500,000	5 million
7.	3	...	...	...	...	...	...	1,000
8.	3	...	...	...	...	...	...	1,000

March 13, 1912: The intradermal test of Romer was applied to calves 1-6; 50 mg. O. T. was used for each calf. Calves 1, 2, 4, 5 and 6 were positive.

March 21, 1912: The same test was repeated, and all calves, including Calves 7 and 8, were positive.

April 10, 1912: Given subcutaneous tuberculin test and all temperatures taken for thirty-six hours. Calves 1, 7 and 8 were considered suspicious.

April 12, 1912: Calves 5 and 6 killed. Necropsy: One left internal iliac gland in each contained hard calcified healed tubercles. All other glands normal. Otherwise negative.

Oct. 1, 1912: Subcutaneous tuberculin test repeated. Calf 1, typical reaction. Calf 3, not typical reaction but is sick clinically.

Oct. 8, 1912: Calves 1 and 3 killed. Necropsy: Calf 1, fat and in fine condition. No tuberculosis found anywhere. Calf 3, thin and small. One large gland filled with pus on outer side of each thigh at site of inoculations. Pus contained tubercle bacilli. Other glands and rest of body entirely negative.

June 15, 1914: Calves 2, 4, 7 and 8 have been since tested, once with the subcutaneous, and three times with the intradermal method, during the last two years and all tests have been negative.

Chart 8.—Temperature chart of Monkey 22.

Inasmuch as 1,000 bacilli of this culture were able to produce infection in calves 3 weeks old, the amounts given were entirely too large and the increase in dosage far too rapid. Only one calf, Calf 3, had clinical tuberculosis, calcified tubercles were found in two, and still another gave no microscopic evidences of tuberculosis.

The fact that calves 7 and 8 apparently overcame completely the mild infection produced is of interest.

3. Webb and Williams: Immunity Production by Inoculation of Increasing Numbers of Bacteria Beginning with One Living Organism, Tr. Sixth International Congress on Tuberculosis, 1908.
4. Webb, G. B., and Williams, W. W.: Immunity in Tuberculosis: Its Production in Monkeys and Children, THE JOURNAL A. M. A., Oct. 28, 1911, p. 1431.

The Barber technic has been of great service in studying the effect of subcutaneous inoculation of minute doses of tubercle bacilli. In the infection of human beings by Nature it has been thought that the bacilli can pass through mucous membranes without the production of a local lesion. In the usual laboratory studies a local lesion following subcutaneous inoculation has been regarded as a *sine qua non*, and an infection of neighboring glands has been predicated.

In a series of guinea-pigs inoculated with minute (from 10 to 60 tubercle bacilli) infective doses sub-

Chart 9.—Temperature chart of Monkey 23.

cutaneously, we have frequently observed the absence of a local lesion, but practically never have failed to find the local glands infected as the following specify:

1. Glands infected but no local lesion, fifty-five guinea-pigs.
2. Glands infected and local lesions, twenty-five guinea-pigs.
3. No glands infected or local lesion, but splenic infection, two guinea-pigs. (These, however, had platelets added to the bacilli.)
4. Failed to become infected, five guinea-pigs.

Our experience with both the intradermal and subcutaneous tuberculin diagnostic tests in monkeys has been rather uncertain and decidedly unsatisfactory. Monkey 6 gave repeated negative results to varying amounts of O. T. given intradermally, and then died with extensive, scattered tuberculosis.

Monkeys 8, 10 and 11 gave positive reactions to 20 mg. O. T. given intradermally, but complete necropsies failed to show any tuberculosis. No rise of temperature after the subcutaneous inoculation of tuberculin has been observed. Interference with the normal night drop has occurred rather frequently, as in Monkeys 9 and 12 when the necropsies were completely negative and in Monkey 20, when a small amount of tuberculosis was found at necropsy. Certainly repeated tests would seem necessary to decide whether or not a monkey had been infected.

In our report⁴ on immunity in tuberculosis in 1911, mention was made of two children inoculated with Culture B.

The children to-day (June 11, 1914), are negative to the von Pirquet reaction, using 100 per cent. O. T. Five other children were later reported on, but Culture B, which was employed, was found to have become avirulent, 200,000 bacilli of this culture failing to infect guinea-pigs.

One of these children (L), however, was so badly exposed, living in a three-room house with an inebriate consumptive in the last stages, that an effort was made to immunize if possible with a more virulent culture. At that time the graded inoculation of this culture (Brown C₄) had not infected a guinea-pig. The child was inoculated beginning Jan. 20, 1913, at seven-day intervals with 2, 3, 5, 7, 10 and 12 bacilli, respectively. Immediately previous to the inoculations a von Pirquet test was doubtful or negative.

March 1, 1913: A slight nodule observed on right forearm at site of a former inoculation. This nodule was at first mistaken for a staphylococcus infection.

March 10, 1913: Foregoing nodule larger. A second smaller nodule 2 inches distant, and a very minute nodule on left forearm.

March 11, 1913: These three nodules removed under chloroform anesthesia. The section of larger nodule showed numerous bacilli.

March 18, 1913: A gland noticed in right axilla enlarged. Removed.

June 14, 1914: Temperature taken through four months remained constantly normal. Child in perfect health. No evidence of glandular enlargement anywhere. Platelets, 396,000. Lymphocytes, 50 per cent. Von Pirquet tuberculin test positive.

BLOOD-PLATELETS AND TUBERCULOSIS

It has for a long time been observed that blood-platelets are increased in tuberculous infection. Osler, however, has written a scathing rebuke to the tyro who every little while claims to recognize tuberculous infection by increase of these blood elements. It seemed wise to try and investigate why Nature increases these so-called third corpuscles, knowing how rarely if ever she operates without a purpose. We have published elsewhere⁵ the following results of our observations.

1. Blood-platelets are increased in the tuberculosis of man and guinea-pigs.
2. Blood-platelets added to a small infective dose of virulent tubercle bacilli appear to modify the infection when injected into guinea-pigs.

In addition we have observed that blood-platelets are increased 12 per cent. in the blood of man and guinea-pigs at an altitude of 6,000 feet. They are also increased by hyperemia of the marrow of long bones and in poisoning by carbon monoxid.

The increase of blood-platelets in the infected Monkey 21 occurred two weeks after the inoculation of virulent tubercle bacilli, and was maintained. The number in the control animal, Monkey 23, remained consistently normal, and post-mortem examinations gave evidence that the findings had been correct.

CONCLUSIONS

1. Guinea-pigs can probably not be immunized with virulent human tubercle bacilli of cultures from which ten bacilli can cause infection.
2. The minimum lethal dose of different virulent cultures would appear to vary in number.
3. The minimum lethal dose for a *Macacus rhesus* is possibly a little larger than that for a guinea-pig.
4. It is necessary to be guided by the virulence of human tubercle bacilli as tested in the guinea-pig before the application to children.
5. After four years two children each inoculated up to five times the lethal dose for a guinea-pig are still negative to the von Pirquet reaction.

5. Webb, Gilbert and Havens: *Colorado Med.*, January, 1914; Trans. Tenth Annual Meeting Nat. Assn. for Study and Prevention of Tuberculosis.

6. In monkeys the decrease of lymphocytes as indicated in differential blood-counts would appear to be more reliable in indicating tubercle infection than the tuberculin tests.

7. Less than ten virulent human tubercle bacilli can infect a child.

ABSTRACT OF DISCUSSION

DR. WILLIAM OPHÜLS, San Francisco: What were the anatomic findings in the monkeys that were so infected? Using these very small doses of tubercle bacilli for the infection, one approximates, I presume, the natural infection more closely.

DR. G. B. WEBB, Colorado Springs, Colo.: No observations were made on the tuberculous monkeys except as stated in my paper. We usually killed the monkeys immediately infection was recognized, as indicated either by a local lesion or glandular swelling.

LYMPHOCYTOSIS AS A SIGN OF CONSTITUTIONAL DERANGEMENT IN CHRONIC DISEASES OF THE DIGESTIVE TRACT*

JACOB KAUFMANN, M.D.

Professor of Clinical Medicine in the College of Physicians and Surgeons, Columbia University; Attending Physician to the German Hospital

NEW YORK

Of an extensive literature devoted to the rôle which constitutional factors play in the development of disease, only a small part deals with the digestive tract. In the discussion of gastro-intestinal diseases the local anatomic aspect dominates the conception of the morbid state. This conception is principally based on the demonstration of anatomic lesions at abdominal operations, which undoubtedly in many instances cleared up the true nature of a formerly obscure process. This applies, however, in particular to acute diseases; we cannot say as unreservedly that the demonstration of anatomic lesions has satisfactorily cleared up the pathogenesis of chronic diseases of the alimentary tract. In most of these chronic diseases anatomic lesions usually are the end-results of a pathologic process, but they do not necessarily indicate its working. For the understanding of its development, pathologic physiology promises better information than anatomic facts. It becomes more and more clear that disturbances of function are the causative factors of pathologic conditions in the alimentary tract: the irritative and the depressive disorders of motility and of secretion, spasm and atony, and increased and diminished secretion of the various digestive glands. When I discussed this topic last year,¹ I pointed out the necessity for studying the conditions which provoke the disorders of function. In this paper I intend to show that a general constitutional derangement very often forms the basis for the development of functional disturbances.

It has been demonstrated that the vagus and the splanchnic influence the activity of the digestive organs, although we know comparatively little of the manner in which the functioning of these opposing nervous apparatus is physiologically regulated. On the

other hand, we have learned to recognize pathologic states or irritation of both nervous systems, the "vagotonia" and "sympathicotonia" of Eppinger and Hess.² Since these authors first differentiated the two conditions, other investigators have pointed out³ that often there are in a given case as many vagotonic as sympathicotonic symptoms, so that the sharp lines between the two states as originally drawn by Eppinger and Hess should be modified. Aside from this the inauguration of visceral neurology marks a decided progress. The knowledge of chronic vagus irritation has thrown considerable light on the pathogenesis of gastric ulcer, and one may expect that further investigation of the vegetative nervous system will clear up many unexplained points in the diseases of the digestive tract.

For the present discussion I wish to call attention to the fact that patients with vagotonic or sympathicotonic symptoms at the same time very often present signs of disordered internal secretions. The relation between disturbances of the ductless glands and those of the vegetative nervous system has not been safely established. Two years ago Dr. Cannon⁴ pointed out the possibility that the glands of internal secretion play a rôle in causing disturbances in the nervous system of the alimentary canal. Dr. Cannon's work deals especially with the effect of excessive secretion of the adrenals, which affects the alimentary canal precisely as splanchnic impulses affect it, by producing a total abolition of tone and a consequent inhibition of all activity.

There is much in the clinical picture of patients with chronic gastro-intestinal diseases which strongly suggests that the influence of disordered internal secretions, in particular of the thyroid gland, is frequently the primary factor which causes the derangement of the visceral nerves. Knowing the importance placed on lymphocytosis in disordered thyroid, I have tried to find out whether blood examinations would offer a firmer basis for such a conception. I have examined 140 patients who presented the different types of chronic functional and organic gastro-intestinal diseases, from plain constipation to gastric ulcer, combined with more or less numerous signs of vagus—or sympathetic irritation. I have purposely abstained from any attempt at classification. The point which I want to emphasize is the remarkable frequency of lymphocytosis which I have encountered in this series of cases.

In my classification of lymphocytosis I considered:

1. As normal a total of 10,000 white cells or less with a differential lymphocyte count up to 35 per cent.
2. As relative lymphocytosis a total white-cell count below 10,000 with a differential lymphocyte count above 35 per cent.
3. As absolute lymphocytosis a total white-cell count above 10,000 with a differential lymphocyte count above 35 per cent.

In the differential classification of lymphocytosis mononuclears and all transitional forms were excluded, while the small and the large lymphocytes counted together were given as lymphocyte percentage.

* Eppinger and Hess: Die Vagotonie, Von Noorden's Samml. klin. 9 and 10.

† For fuller information regarding these questions see: Hemmeter: Med. Jour., 1914, p. 101. Wolfsohn, J. M.: The Normal Physiologic Physiology of the Visceral Nervous System, THE A. M. A., May 16, 1914, p. 1535.

‡ President's Address. Tr. Am. Gastro-Enterol. Assn.,

Of the 140 cases examined, 43 showed a normal lymphocyte count; 7 were on the border line; 16 showed absolute lymphocytosis, and 74 showed relative lymphocytosis. Of the latter 11 showed leukopenia, that is, a total white-cell count below 6,000, downward to 3,200.

Of the total number of 90 cases of lymphocytosis (16 absolute and 74 relative):

From 35 to 40 per cent. of lymphocytes were shown by 27.
From 41 to 45 per cent. of lymphocytes were shown by 18.
From 46 to 50 per cent. of lymphocytes were shown by 20.
From 51 to 55 per cent. of lymphocytes were shown by 20.
From 56 to 62 per cent. of lymphocytes were shown by 5.

The ninety cases of lymphocytosis represent 60 per cent. of all cases examined. Since a number of these patients reported only for mild temporary disorders and were examined as a routine, the 60 per cent of cases showing relative or absolute lymphocytosis must be considered very high.

The question is, What does lymphocytosis indicate? The examination of my patients soon made me realize that lymphocytosis is by no means as reliable a sign of exophthalmic goiter as it was formerly considered. Only a few of my patients presented symptoms which could be interpreted as caused by hyperthyroidism. I then found from the literature that during the last few years a different meaning had been given to lymphocytosis. Kocher's clinic, as Pettavel's⁵ recent publication shows, still adheres to the original conception of lymphocytosis as a direct result of hyperthyroidism. This view, however, has been challenged by a number of writers. Borchardt,⁶ Falta,⁷ and Maranon⁸ were among the first to point out that lymphocytosis is observed not only in hyperthyroidism but also in hypothyroidism, and, further, in disturbances of the other ductless glands such as the hypophysis, the adrenals, etc. These authors assert that the ductless-gland disorder is the primary disturbance, which in turn produces status lymphaticus, and they consider the lymphocytosis as a manifestation of status lymphaticus.

The linking of lymphocytosis and status lymphaticus has complicated matters so far as one forgets that we are dealing here with two distinctly different problems; first, with the relation of lymphocytosis and ductless-gland disorders, and second, with that of lymphocytosis and status lymphaticus. The definition of status lymphaticus is anything but clear. In literature we often find the diagnosis status lymphaticus merely based on the findings of blood-lymphocytosis, without any reference to the fact that these cases presented the hypertrophy of the lymphatic tissues or any of the other anatomic features, which Palttauf, and after him Kolisko, Bartel and Neusser have given as the main criterion of status lymphaticus.⁹ A good deal of confusion might be avoided if we followed Bartel,¹⁰ who proposed to confine the term "status lymphaticus" to the group of cases which are anatomically well defined by hypertrophy

of the lymphatic tissues, and differentiated this group from what he calls status hypoplasticus, which in a less restricted and broader conception denotes a general constitutional inferiority with more or less marked hypoplasia in various organs and with lymphatic systems which, although not hypertrophic, nevertheless show abnormalities. If we accept this differentiation it must be stated that according to Siess and Stoerck,¹¹ no lymphocytosis is found in true status lymphaticus, so that there is no justification for regarding lymphocytosis as an indication of status lymphaticus, as is done by most writers at present. If the findings of Siess and Stoerck are corroborated it must be declared an error to diagnose status lymphaticus merely because lymphocytosis is present. On the other hand, lymphocytosis is very frequently found in cases which answer Bartel's description of status hypoplasticus or whatever one may call this condition of general constitutional inferiority. Kahler¹² pointed out that lymphocytosis may be considered in a more general way as a manifestation of that constitutional derangement which in literature is differently described as lymphatism, lymphatic constitution, status hypoplasticus, general congenital asthenia, morbus asthenicus, infantilism, etc. This constitutional derangement is met very frequently. It may give rise to disturbances in various systems, a fact which accounts for the demonstration of lymphocytosis in so many different conditions. To quote only a few of a great number of publications: Von Hösslin¹³ and Sauer¹⁴ report the frequency of this blood-picture in all functional disorders of the nervous system which such patients are particularly prone to develop. Gudzent¹⁵ found lymphocytosis in chronic arthritis, so frequently associated with status hypoplasticus; Mohr¹⁶ in constitutional obesity, and Decastello¹⁷ in tuberculosis. The correlation of lymphocytosis and status asthenicus as developmental anomalies and predisposing factors for tuberculosis have often been discussed, lately by Bartel and Kraus.¹⁸

In the majority of my cases with lymphocytosis I noted a more or less pronounced tendency to asthenia or other manifestations of status hypoplasticus.

If it is permitted to conclude from all these findings that lymphocytosis may be taken as an indication of status hypoplasticus, the figures in my series certainly show that this constitutional derangement frequently forms a basis for the development of diseases in the digestive tract.

I have to come back once more to the question, What relation exists between lymphocytosis and disordered internal secretions? I quoted above the opinion of Kocher and others, who consider the blood-picture as secondary to the ductless-gland disorder. So far there is little proof for this contention and much may be said against it. In the first place it is difficult to understand how, as Borchardt and Falta assert, the same blood-picture should be produced by entirely different ductless-gland disorders—by decreased as well as increased thyroid secretion. I further call attention to Kocher's own reports which show that lymphocytosis remained unchanged in cer-

tain cases of exophthalmic goiter after the overactivity of the gland was successfully checked by operative treatment. This suggests that lymphocytosis is an indication of some factor other than hyperthyroidism.

In his monograph on status lymphaticus, Neusser¹⁹ suggests the possibility that the lymphatic tissues produce a secretion which acts as the antagonist of epinephrin, and that abnormal lymphatic tissues may cause a disturbance of this secretion, which in turn upsets the activity of the other ductless glands. More light will have to be thrown on this problem before we can speak of a causal relation. Until then it seems safer merely to record that lymphocytosis and ductless-gland disorders are frequently associated, or, to express it differently, that persons with status hypoplasticus are inclined to disorders of internal secretions. It seems that they are particularly predisposed to thyroid insufficiency, possibly on account of fatigue when more demands are made on them than their constitutional derangement permits them to bear.

In my series of cases, symptoms of thyroid insufficiency were decidedly predominant. I wish to mention here that in 1907 Dr. Sawyer²⁰ discussed the frequent relation of digestive disorders and thyroid disturbances and reported diagnostic blood-pictures. Dr. Sawyer designated his cases as incomplete forms of exophthalmic goiter. Most of my own cases presented symptoms which, according to the teaching of Hertoghe, Levi and Rothschild, Saenger and others, are the result of the thyroid insufficiency, so that instead of *formes frustes* of Graves, one should speak of *formes frustes* of myxedema, or as others have called it, of chronic benign hypothyroidism. The correct interpretation of the thyroid disorder is important for purposes of treatment. It is true that we should not differentiate too sharply, since it is known that overactivity as well as insufficiency of the thyroid may at different times occur in the same patient; and then, too, it is becoming more and more evident that thyroid disorders are rarely observed alone, but that as a rule they are combined with other ductless-gland disorders; yet there can be no doubt that in most cases one type of disorder is distinctly preponderant.

Of the signs attributed to hypothyroidism observed in my patients the most frequent symptoms pointing to retarded metabolism were: congestion of the liver associated with bilious attacks, headaches and migraine; tendency to fatigue, lack of ambition, mental depression, low blood-pressure, impaired circulation and cold extremities. In most of these cases a small thyroid gland was found which permitted palpation of the tracheal rings down to the sternum. Of the symptoms referable to the alimentary canal, I mention atony of the stomach and intestines with constipation and congestion of the mucous membranes causing a tendency to chronic inflammatory processes; when associated with symptoms of vagotonia, irritative disorders of the stomach, hyperacidity and hypersecretion, spastic conditions in various parts of the digestive tract from the esophagus down to the anus with all its sequelae, gastric ulcer, spastic constipation, mucous colitis, adhesions following inflammatory processes in the various organs and their mechanical results.

I wish to state that I observed some cases with symptoms of hypothyroidism in the digestive tract as

well as in other organs which showed no lymphocytosis, although their number was small as compared with the number which presented lymphocytoses.

In a number of cases presenting symptoms of hypothyroidism I had excellent results from the administration of thyroid. This was particularly instructive in cases of children suffering from malnutrition who were subject to gastric atony, constipation, congestion of the liver, headaches, etc., and who were freed of these disorders by thyroid medication. I observed cases of gastric hyperchlorhydria which had stubbornly resisted all other methods of treatment, and which then were relieved by taking thyroid. The same beneficial effect of thyroid therapy was experienced in other gastro-intestinal disorders when they were associated with chronic benign hypothyroidism.

I shall not discuss any further ductless-gland disorders and thyroid therapy, and I shall be very careful not to generalize. The report of successful thyroid treatment in my cases was merely meant to show that there are possibilities of causative treatment once we recognize the constitutional derangement and the disorders which it leads to. But valuable as such more specific forms of treatment are, there is a more important lesson to be learned from the present discussion; and this is, that the constitutional factor which I so often found at the bottom of chronic gastro-intestinal disorders should be given full consideration in the general management of such patients.

The periodicity which characterizes most chronic digestive disorders indicates that general conditions, such as constitutional derangements, are the decisive factors in the development of the disorder and not the anatomic lesions which are end-results. This is particularly evident in gastric-ulcer cases; and whether when treating them we shall succeed in avoiding recurrences will not depend so much on the employment of any special form of ulcer treatment, and in operative cases not on improved technic or new methods of operation, but it will depend to a much greater extent on our ability to regulate the patient's mode of living and on the patient's ability to observe general hygienic and dietetic principles and rules, which consider not only his local disorder, but in the broadest possible way his constitutional make-up, his mental state, his work, his habits, etc.

We are fully familiar with such conceptions for other diseases. It is generally understood that epilepsy develops on the basis of a constitutional disposition, and that this disposition must constantly be the object of treatment no matter whether the individual attacks are provoked by constipation, by the irritation of scar tissue, or from any other cause. There is no difference of opinion regarding the necessity of persistent hygienic and dietetic treatment in tuberculosis, if we want to succeed in fighting the ravages of the tubercle bacilli; and this is precisely the same situation which confronts us in many chronic gastro-intestinal disorders. We must emancipate ourselves from the narrow view which considers only the local disorder, be it ever so pronounced, and take into account the fact that a constitutional derangement is often the basis for the development of most of these local disorders, and that this constitutional derangement necessitates as persistent general treatment as it does in epilepsy, tuberculosis and other diseases. I hope that I have made this clear.

THE SPECIFIC ACTION OF SALICYLATES IN
ACUTE ARTICULAR RHEUMATISM*

JOSEPH L. MILLER, M.D.

CHICAGO

Maclagan in 1874 was apparently the first physician to ascribe to salicylates a specific action in the treatment of acute articular rheumatism, although in the discussion following his report an English army surgeon in South Africa related that a decoction of willow bark was a favorite remedy among the Hottentots in the treatment of painful joints. His use of the remedy was purely empirical. He believed, on account of the profuse perspiration, that rheumatism was closely related to malaria; that in certain regions where malaria is prevalent the cinchona grows and that, therefore, in local surroundings especially favorable for the development of rheumatism, search should be made for a specific. As dampness predisposes to rheumatism, the search was begun among those plants growing in low grounds; early he examined the willow, and from this obtained the salicin, which he hailed as a specific.

The following year (1875) Buss and Riess,¹ and also Stricker² apparently independently of Maclagan recommended, on account of its antiseptic power, salicylic acid. Senator in 1876, also independently of Maclagan, recommended salicin, as, according to Ranke, Lehman and others, it was converted into salicylic acid in the stomach. The introduction of salicylic acid at this particular time can be accounted for by the introduction in 1874 of Kolbe's process of manufacturing it. Although salicylic acid was first made by Pagenstecher in 1835, it was not until Kolbe's discovery that it could be produced at a moderate cost.

The use of the salicyl preparation in rheumatism became quite general in both England and Germany during the late seventies, and especially in the English medical journals of that date an interesting discussion was carried on as to whether or not this group of drugs really possessed great therapeutic value in arthritis. On either side of the question could be found some of the best medical men of the day. It is largely from the literature of this period that we can obtain abundant statistical data.

Regarding the supposed method of action, this was considered purely bactericidal, the first preparation used in Germany being salicylic acid, which, as is well known, is a very powerful germicide. It is a general cellular poison, toxic to the cells of the body, and, as far as we know, has no selective action for bacteria. It was overlooked at this time that the salicylic acid on leaving the stomach is converted into a salicylate and appears in the circulation and comes in contact with the tissues in this form. If, therefore, its action is bactericidal, it must be reconverted in the tissues into salicylic acid. Salicylic acid is rapidly and completely eliminated through the kidney chiefly in combination with glycocholic acid, as salicyluric acid; a very small amount may be excreted as salicylic acid. Inasmuch as drugs may have a selective action for certain tissues, it is possible that this selective action may be

manifested by the inflamed joints, and if so there may be conditions present making possible the conversion of the salicylates into the salicylic acid. Fillipi and Nesti have shown that in man two hours after the administration of acetylsalicylic acid a test for salicylate could be obtained from the synovial fluid. Bondi and Jacoby³ gave rabbits 0.57 gm. of salicylic acid and later determined its presence in the various fluids and tissues of the body. They found much larger amounts in the muscles and joints than in other tissues, and at times it could be demonstrated in the cartilage and synovial membrane and not in other tissues. They did not show, however, in what combination the salicylic acid existed. This is after all the most important point, as the salicylates do not have any germicidal action.

As all the tissues of the body have an alkaline or neutral reaction, the sodium salicylate cannot be converted into salicylic acid in the tissues unless, as Binz⁴ has suggested, in the presence of increased carbon dioxide tension. Both Binz and Ewald⁵ were able to show that the carbonic acid tension is from 5 to 7 per cent. higher in inflamed tissues than it is in the blood, even in extreme cyanosis, and that the blood in extreme cyanosis is capable of freeing the salicylic acid from its salt. Binz also demonstrated that an alkaline fluid containing sodium salicylate, if impregnated with carbonic acid to the degree found in inflamed tissues, would permit of the breaking up of sodium salicylate, and the setting free of salicylic acid. Although this has not been shown to actually occur in the joints in arthritis, on theoretical grounds it is at least possible.

Previous to the introduction of salicylic acid, acute arthritis was treated by the use of alkalies, heat, counter irritation and venesection. Under these methods, the results of treatment were generally conceded as better than with the expectant method. With the introduction of salicylic acid, there was abundant opportunity for comparative observation of the value of this new therapeutic agent. These observations consisted of statistical collections and personal impressions. It is of interest to note that even at this time the best men in the profession did not consider the drug as a specific in the sense we use this term with quinin or mercury, but rather debated whether this new treatment was superior to the old. On account of the variable duration of the disease, the sudden improvements and relapses, it is extremely difficult to draw accurate conclusions, except by carefully compiled statistics extending over a considerable period of time. Southey⁶ most appropriately stated in 1879 at the time when the discussion of the value of salicylates was at its height that "there are few diseases, perhaps, which present more dangerous pitfalls to the unwary and clinically ill informed in therapeutics than rheumatism." Before the use of salicylates, Southey, Gull and Sutton, and others had divided acute articular rheumatism into two groups: one in which the disease ran a short course, the symptoms all subsiding about the eighth or ninth day; a second, relapsing type when about the eighth or ninth day a mitral murmur appeared, and in these cases the apparent recovery was followed by a relapse which might continue for sev-

eral weeks. These observations are of interest as suggesting the possible importance of endocardial involvement accounting for the relapses and protracted duration.

In considering statistics two points have been observed: the time of disappearance of pain after entering the hospital, and the average period that patients, with and without salicylates, remained in the hospital. These two points were selected, first, because the pain, while purely subjective, yet is so constant that its subsidence may be considered as a fair index of the disappearance of the acute symptoms. On the other hand, relapses are so frequent and moderate tenderness so often persists long after disappearance of the acute pain that the patient's statement must often be considered relative; for this reason the period of time spent in the hospital may be taken as the time required for an actual cure plus the necessary period of convalescence. On account of the antipyretic action of the salicylates, the duration of the febrile period is of little value. In going over the literature all extensive series of cases in which these two points were recorded have been taken; unfortunately from the standpoint of accuracy, the number of observers is small. While both sets of figures are based on the duration of the disease from entrance to the hospital, rather than from the time of actual onset, for comparative purposes this does not impair the result.

Considering the first point—the time at which pain disappeared after entering the hospital—Reihler⁷ reports 638 cases with salicylate, average duration of pain being 5.1 days; 425 cases without salicylates, average duration of pain 9.8 days. Pribram⁸ reports 541 cases with salicylates, with average duration of pain 6.5 days; 354 without salicylates, average duration of pain 10.4 days. Reisz treated 79 cases with salicylates, the average duration of pain being 5 days, and 124 without salicylates, with average duration of pain 21 days. In all 1,258 patients were treated with salicylates with average duration of pain 5.3 days, 974 without salicylates, average duration 13.4 days. In addition, Hood⁹ reports 350 cases, in 80 per cent. of which under salicylate the pain disappeared within 9 days and 311 without salicylates, with disappearance of pain in only 40 per cent. of cases within 9 days.

These statistics show that the duration of pain in the joints is much lessened by the use of salicylates. Still, 30.3 per cent. of those receiving salicylates, but only 6 per cent. of the untreated, have one or more relapses, and this was not considered in the statistics, as the time reported is that of the first disappearance of pain. For this and other reasons, especially the absence of the personal equation, the average period of time the patients remained in the hospital is probably more accurate and of more value.

Fortunately, extensive statistics on the time that patients remained in the hospital previous to and since the introduction of salicylates are available.

Perhaps one of the most striking features of these statistics is the uniformity of the period spent in the hospital. These figures include all the available extensive series except 417 cases given the alkaline treatment by Fuller and reported in 1863, in which the average period in the hospital was 20.1 days. As these

figures are so at variance with those reported by others using the same treatment, they have been purposely omitted from the table. At this early period of salicyl therapy the dosage was large; 15 to 20 grains every two to three hours was considered a moderate dose and many gave 300 grains a day. For this reason the criticism cannot be urged of insufficient dosage.

The information to be drawn from these statistics is that the pain and evidence of active inflammation in the joint is controlled at least temporarily by salicylates. On account of relapses and slight joint involvement, the actual complete recovery of the patient has not been materially modified by the use of salicylates. It would appear that the drug shortened the period of local inflammation in the joint, and apparently prevented new joint infection. The generalized infection, however, ran its usual course. This may be due to the bactericidal action of the salicylic acid which is set free owing to the increased carbonic acid tension in the inflamed joint. None of our present theories, however, provide for the presence of free salicylic acid in uninflamed joints, which would be necessary in order to account for failure of new joints to become involved after the use of salicylates. Fre-

quently, however, in spite of the use of salicylates the joint infection continued to recur, either not being affected by the salicylates, or, after being held temporarily in abeyance, again becoming active. Relapses may occur even while the patient is receiving large doses of salicylates; in one report a relapse occurred while the patient was taking daily doses of 13 gm. Miller¹⁰ in a recent review of this subject states that of seventeen relapses, eleven occurred while the patient was still taking salicylates. Five of these were taking daily not to exceed 50 grains, four not to exceed 100 grains; one taking 150 to 200 grains; one taking 200 to 250 grains. These patients were all children and while the ages of these particular patients are not given, judging from references elsewhere in the article, they were probably under 10 years. The temporary improvement with later relapses lead to the view that salicylates were responsible for these. It is probable, however, that in the untreated cases the course of the disease was unmodified, while in those receiving the salicylates temporary lulls occurred in the local manifestation.

10. Miller, R.: The "Specific" Use of Salicylates in Acute Rheumatism: A Consideration of Practical Objections, Quart. Jour. Med., July, 1913, p. 519.

It would appear that salicylates are not the only therapeutic measures which affect favorably the acute symptom of rheumatism. High degrees of heat may act in much the same manner, causing the acute pain to disappear, only to return again after the treatment has been discontinued. So accustomed are we to use salicylates freely in all patients with acute arthritis that we are not in a position to judge of its value compared with other forms of treatment. During the past winter, for a period of two months, all acute arthritis patients on my service at Cook County Hospital received sweats and alkalies, but no salicylates; the temporary results were most gratifying. Tenderness and stiffness almost invariably disappeared within a week and the patient reported he was well. Within a week of the time the treatment was discontinued, however, 30 per cent. of these cases relapsed. The results, however, were very interesting, as shown that other agencies than salicylates have a decided favorable action on the acute symptom of acute articular rheumatism.

From the information at hand it would not appear justifiable to refer to the salicylates as a specific in acute articular rheumatism but rather as a drug which modifies the course of the disease, without actually shortening the period of infection.

All authorities agree that salicylates have not lessened the frequency of cardiac complication. Taking Pribram's statistics collected from various sources, 28.8 per cent. of cases receiving salicylates and 23.4 per cent. without salicylates developed cardiac complication.

Regarding the dangers of salicylates, these are confined chiefly to the effect on the kidney. It is very doubtful whether the condition ascribed by Lees to acid intoxication was really due to the drug, but rather to the intoxication from the disease. We have evidence from several sources that salicylates irritate the kidney and may excite a mild nephritis: Klieneberger and Oxenius,¹¹ Luthje, Frey and Glaesgen.¹² The disturbance, however, is temporary and soon subsides even though the salicylates be continued. According to Frey, the kidney irritation can be largely avoided by the use of alkalies. Gastric disturbances are common but not of a serious character, as they promptly subside when the drug is discontinued. Large doses at times may produce symptoms of collapse with slowing of the pulse and respiration. Seiler reports the death of a 7-year-old child after 5 gm. of sodium salicylate; Hogg, a death after two doses of 2 gm. each; Gubler, one after 10 gm.; Goodhart, one after doses totaling 3.6 gm. Quincke reports a death, in which the predominant symptom was dyspnea, after a three days' daily dose of 12 gm.

Since it has been possible to obtain cultures of a streptococcus from the joints of men with acute articular rheumatism, it might be thought possible to determine the effect of salicylates by a bacteriologic study of the joint contents. This is apparently impossible on account of the very transient presence of the germ in the affected joint. Rosenow has found that the micro-organism can be obtained only when cultures

are made within a few hours after the appearance of the joint involvement. There remains the field of animal experiments, as joint involvement analogous to the acute articular rheumatism of man can be produced in rabbits by intravenous injection of the streptococcus obtained from the joints of man. Rabbits might be infected and one group then given salicylates and the remainder used as controls. Cultures could be made from the joints at frequent intervals to determine whether the micro-organisms are less abundant or disappear more rapidly in the treated animal. Here again the inconstancy of positive cultures and the difficulty of obtaining sufficient fluid from the joint to make a culture render this method unsatisfactory. Furthermore, frequent puncture of the joint is liable to lead to secondary pus infection. Another method of procedure is to place the animal under salicylates before the inoculation and determine whether this has any effect on the rabbit's susceptibility to joint involvement. If the salicylates act through their germicidal properties, it should be manifested in an experiment of this character.

Young rabbits were selected, as they are much more susceptible to joint infection. The salicylate in 5-grain daily doses was given subcutaneously. This dosage is not excessive, being equivalent to about 250 grains in man. It is true that this was given in a single dose, but none of the rabbits showed any immediate ill effects. Two series of six rabbits each have up to the present time been submitted to this test by Dr. D. J. Davis. In one series a streptococcus was obtained from the tonsils of a patient with acute arthritis; a second series was inoculated with a culture obtained by Dr. Rosenow directly from the joint of a patient with acute arthritis. In each series three rabbits received the salicylate for several days preceding and for a week or more following the inoculation. The other three rabbits did not receive salicylates. The six rabbits received simultaneously an intravenous injection of streptococci. The animals were then examined daily, the number and extent of joint involvement noted, and after the lapse of a week the animals were killed; the involved joints opened and examined. The two series of six rabbits each submitted to this test did not show that the salicylates had any effect either in preventing joint involvement, or modifying the intensity of the same. At a later date when this work is completed it will be published in detail.

SUMMARY

As salicylic acid after absorption circulates and appears in the tissues as a salicylate, it cannot act as a germicide unless the increased carbonic acid tension in the joint, the result of inflammation, reconverts it into salicylic acid. Statistics show that patients receiving salicylate are free from pain much earlier than those not treated. As the treated patients much more frequently relapse than the untreated, however, the total duration of pain in the treated and untreated patients may not be materially different. The period of stay in the hospital of patients receiving salicylate and of those receiving other forms of treatment is the same. Cardiac complications are not less frequent since the use of salicylates. In rabbits the prophylactic use of salicylate is of no value in preventing arthritis after intravenous injections of hemolytic streptococci.

ABSTRACT OF DISCUSSION

DR. WARREN COLEMAN, New York: My experience with salicylates in acute rheumatic fever is not in accordance with what would appear from Dr. Miller's analysis of cases. Has Dr. Miller considered the size of the doses which were used in certain cases? Some years ago a paper by Lees appeared in the *British Medical Journal*. His treatment of rheumatic fever with the salicylates differed materially from any which I had seen described. He recommended the use of salicylate up to 500 or 600 grains a day. I continued, however, to use 20 grains of a salicylate every two hours and 40 grains of sodium bicarbonate until recently, when the size of the dose has been increased. I have been greatly gratified by the results. Lees believes that the salicylates are just as specific for this disease as salvarsan is for syphilis or quinin for malaria. While I am not prepared fully to endorse this statement, the symptoms of the disease usually disappear in from twenty-four to thirty-six hours after the administration of the large doses. Lees states that the salicylates should always be combined with twice the quantity of sodium bicarbonate as otherwise a condition resembling acidosis may develop. Another point he makes is that the drug should be discontinued on any day that the patient's bowels do not move.

DR. LAWRENCE LITCHFIELD, Pittsburgh: Has Dr. Miller collected any observations as to the frequency of endocarditis? Krause believed that cases with full salicylic acid treatment showed a smaller percentage of endocarditis; and also in cases of tonsillitis in which rheumatic complications were feared he believed in giving salicylic acid. I know Krause believed in the specificity of salicylates for rheumatism and gave from 0.5 to 1 gm. every hour, day and night, until the patient improved. There was no mention of sodium bicarbonate or acidosis. His convictions must count for something even in the face of these statistics. The question is not whether the patients get salicylates, it is whether they get saturated with them. Krause used salicylic acid in this way and rarely needed to continue it more than twenty-four or, at most, thirty-six hours. When not well borne he gave diplosal, which I have found very satisfactory.

DR. BERNARD FANTUS, Chicago: If I rightly understand the points made by Dr. Miller he did not deny value to salicylates in the treatment of rheumatism. I believe he admitted analgesic value; but the point made is that there was no diminution in the duration of the disease. With both of these propositions I can heartily agree. His statistics show that the salicylates do not seem to have antibacterial action in this disease.

DR. JOSEPH L. MILLER, Chicago: All these statistics were collected between 1876 and 1884. At that time 200 to 300 grains were given daily, so the objection to small doses does not hold good. The only point about Lees' paper which interests me is that relapses will occur and two-thirds of the relapses occur while the patient is taking the salicylates. Relapses, however, are fewer under larger doses than when smaller doses are given. I judge that the salicylates do modify the course of the disease just the same as sweats and heat modify it. The fact that the symptoms return after the stopping of the salicylates is proof of his fact. The duration, however, I believe is not especially modified.

Influence of Arabian Medicine.—The influence of Arabian medicine on modern medicine can, perhaps, best be judged from the number of words in our modern nomenclature, which, though bearing Latin forms, often with suggestion of Greek origins, still are not derived from the old Latin or Greek authors, but represent Arabic terms translated into Latin during the Renaissance period. Hyrtl, without pretence of quoting them all, gives a list of these which is surprising in its comprehensiveness. For instance the mediastinum, the sutura sagittalis, the scrobiculus cordis, the marsupium cordis, the chambers of the heart, the velum palati, the trochanter, the rima glottidis, the fontanelles, the alae of the nose, all have their present names, not from Latin, but from Arabic terms.—Walsh, *Makers of Medicine*.

ARTIFICIAL PNEUMOTHORAX AND PREGNANCY

CASE REPORT

J. J. MAHONEY, M.D.
COLORADO SPRINGS, COLO.

The case cited below is an interesting example of what the human organism may accomplish with a little help, and a striking example of the efficacy of induced pneumothorax under some very unfavorable circumstances.

History.—Mrs. F. W., aged 24, born in Illinois, was referred to me Jan. 1, 1914. Grandparents on both sides lived to 90 years of age and over. Mother died of pneumonia. Father died of pulmonary tuberculosis at age of 36. Two brothers and five sisters are living and in good health. One sister died of pulmonary tuberculosis at age of 19. Patient had none of the diseases of childhood, but has always been very frail. She married at 20 and gave birth to healthy baby boy two years later. She nursed baby for one month. About this date slight cough and expectoration appeared, and the patient had daily afternoon fever and began to lose weight rapidly. In February, 1912, she had sweats nightly for about one month. Tubercle bacilli were demonstrated in the sputum at this time. From February to August, 1912, treatment consisting of rest, outdoor living and forced feeding was tried in Illinois without material gain. In August, 1912, a change to Colorado was advised. Patient entered a sanatorium in Colorado Springs and remained there ten months. Fever gradually declined so that by the end of the third week in the sanatorium, temperature was normal and remained so for over ten months. During the first four months patient gained 22 pounds. Patient left sanatorium in June, 1913, 25 pounds heavier, pulse and temperature at a normal level, but still coughing and raising slightly in the morning. On leaving sanatorium she took up housekeeping, doing almost the entire house work. In August, 1913, she became pregnant. In September cough and expectoration increased considerably and afternoon fever of 100 reappeared. During November and December she lost strength and weight very rapidly, and had afternoon fever ranging from 101 and 102.5 at this period.

Examination and Treatment.—Jan. 1, 1914, patient was referred to me for examination and the performance of artificial pneumothorax if advisable. Physical examination showed a poorly developed and emaciated body. The left lung disclosed signs of active trouble from apex to base. Right lung was apparently clear. Temperature was 101, pulse 110. Artificial pneumothorax was advised.

January 15, temperature at 11 a. m. was 99.6, pulse 112. At 8 p. m., temperature 101.5, pulse 120. Urinalysis: Specific gravity 1.020; no albumin or sugar; no casts.

January 16, the first injection, 900 c.c. gas, was given at 11 a. m. Temperature at 2 p. m. was 101, at 4 p. m. 101.6, at 8 p. m. 101.8. Pulse from 110 to 120. There was considerable pain and no sleep the first night, with abundant expectoration.

January 17, temperature at 8 a. m. was 98.2, 12 m. 99.2, 4 p. m. 99.6, 8 p. m. 100.2, pulse from 100 to 120. Expectoration was considerably less.

January 18, temperature at 8 a. m. was 98, 12 m. 98.8, 4 p. m. 98.6, 8 p. m. 98.6. Pulse from 100 to 110. There was very little expectoration after morning clearing out. On the morning of the 18th a second injection of 400 c.c. was given. Temperature remained normal from this date until two weeks before labor. Pulse ranged from 80 to 86. During this period patient gained rapidly in strength and 15 pounds in weight; cough and expectoration ceased entirely. The injections of gas were continued at regular intervals during the pregnancy.

Two weeks before labor patient had afternoon fever of from 99 to 100. Urinalysis at this date revealed a specific gravity of 1.032; albumin, trace; no sugar; no casts. Fever

continued until two weeks after labor, after which temperature gradually dropped to normal, pulse ranging from 80 to 90, which conditions have existed without variation up to present date. No cough or expectoration. Labor occurred April 29, 1914, was of seven hours' duration and normal in every respect. One hypodermic injection of pituitary extract was administered fifteen minutes before delivery of head.

Recovery was uneventful. Temperature became normal two weeks after confinement, and at the end of the third week patient was able to be wheeled out in chair. Six weeks from date of labor patient was up and out and apparently well in every respect. Gas injections are still being administered at regular intervals.

In my experience with artificial pneumothorax, now numbering over sixty cases, I have had but one case of pregnancy in the series, from which one cannot draw conclusions. I simply wish to add this testimony to other data now in the process of collection, from which some conclusions may be drawn at a later date.

INTESTINAL STASIS

MAX EINHORN, M.D.

Professor of Medicine, New York Postgraduate Medical School
NEW YORK

The term "intestinal stasis" originated with Sir Arbuthnot Lane. The chronic variety of intestinal stasis this eminent surgeon¹ defines as follows:

Such an abnormal delay in the passage of the intestinal contents through a portion or portions of the gastro-intestinal tract as results in the absorption into the circulation of a greater quantity of toxic or poisonous materials than can be treated effectually by the organs whose function it is to correct them into products as innocuous as possible to the tissues of the body.

The main cause for chronic intestinal stasis Lane attributes to visceroptosis and formation of kinks. Bainbridge,² one of Lane's most ardent followers, says:

The natural outcome of this kinking of any portion of the drainage tube is obstruction of the lumen of the intestine at the point of the kink with "puddling" in the dependent portion, damming back and infection of the contents, and general slowing of the drainage of the canal.

The symptoms are briefly, headaches, nausea with vomiting, anorexia, loss of weight, cold extremities, mental apathy, constipation, bad taste in mouth, abdominal distention, muscular pains.

The diagnosis is based on the discovery of existing visceroptosis or intestinal kinks (which are best demonstrated by Roentgen rays), in conjunction with a delay in the intestinal prochoresis. For the recognition of the latter Patterson uses the charcoal test. He gives two teaspoonfuls of charcoal and gauges the time of its appearance in the stool. If charcoal does not appear within sixty hours, there is intestinal stasis.

The treatment consists, in mild cases, in an appropriate abdominal support and the administration of liquid paraffin, and in severer cases, in ileocolostomy (short circuiting the bowel) or colectomy.

This, in short, is a brief résumé of Sir Arbuthnot Lane's teaching.

This subject is not a mere theoretical one but presents issues of great practical importance, dealing sometimes with situations endangering life.

I feel forced, therefore, to lay my views, which are quite contrary to Sir Arbuthnot Lane, before the profession.

I would like to mention first that visceroptosis giving rise to intestinal angulations (designated as "kinks" by Lane, and the formation of partial stenoses with delayed prochoresis, originated with F. Glénard. Whatever credit be due for this conception, it belongs to Glénard and not to Lane.

The second point, that of intestinal stasis leading to the absorption of poisons within the intestine, or auto-intoxication, is a theory which was advanced long ago, principally by French clinicians, Bouchard, Combe, and others. This theory has been made by Lane and his disciples the foundation for their plan of treatment. The digestive canal is called a "drainage tube" and compared to a sewer system, in which any clogging must cause disaster.

For our own satisfaction let me say that our organism is not so poor an engine as it is depicted by the adherents of the "stasis" theory. If our body is resourceful, as you all well know, in adequately fighting enemies that it has never before encountered—pneumonia, typhoid fever, etc.—how much more must we expect from it in the way of every-day defenses. It is surely well fitted to debar the entrance of harmful digestive products through the intestinal wall, for this is a continuous happening.

Unless there is a real mechanical obstruction or some substantial organic lesion interfering with the intestinal current, a temporary delay or stasis of the contents may not mean much. At times this delayed prochoresis may serve to make absorption more complete, and is encountered in instances of insufficient nutrition.

Now a word with regard to the auto-intoxication theory, as far as it concerns intestinal stasis or habitual constipation (for this is only another name for it). Constipation does not cause auto-intoxication. For, occasionally, a patient may have no bowel movement for several days and present no abnormal symptoms whatever. The symptoms frequently associated with chronic constipation may be ascribed to nervous disturbances, and not to auto-intoxication. Reassurance and nerve sedatives will often do more good than drastic measures.

We now come to the last point, namely, that of treatment. In mild cases Lane, following Glénard, recommends an appropriate abdominal supporting bandage. To this I fully agree. In the severer type Lane recommends operative measures; ileocolostomy or colectomy. With this radical plan of treatment most clinicians and some eminent surgeons do not agree.

If we did not need the colon, which is an organ of considerable length, we would not have it, or it would show decided signs of degeneration; but this is not the case.

Ileocolostomy, or colectomy, is justifiable in cases of cancer or stricture of the bowel, but not in functional disturbances. Albu³ has shown that while it is possible to exist without a colon, an individual deprived of this organ is subject to great dangers and easily succumbs to intestinal diseases with which an ordinary person can cope without difficulty.

In addition, there are the dangers of the operation, and ultimately the uncertainty of a cure after exclusion or removal of the colon.

Therapeutics

PREVENTION GREATER THAN CURE

LIFE PROBLEMS

The "survival of the fittest" begins with the germ of reproduction, goes through embryonic life, through parturition, through infant life, through childhood, and presumably should be considered as ultimately satisfied at 20 years of age, but it is not perfectly satisfied until another individual emanating from this "fit" individual of 20 years or more has also reached the age of 20. Such, theoretically, may be considered the "survival of the fittest."

It is the object of this series of articles to cause medical men to review the knowledge already acquired of the means and methods of causing more "fit" to be born, and more "fit" to survive and have their health unimpaired by preventable disease.

To show how lavishly nature provides at the start for the survival of the fittest, it should be noted that each human male having normal sexual health and living until the age of 60 is said to produce more than 300 billions of spermatozoa, while the ovaries of the human female are said at puberty to contain about 30,000 eggs. This is not to suggest that the world would be happier with an enormous increase of individuals, but it will be happier, and there will be less poverty, if there are more normal individuals and fewer abnormal ones. The economic value of wars and plagues need not be discussed, but it should be remembered that the strongest men (the most "fit") are the ones who die in battle, and that pestilences destroy the "fit" as well as the "unfit."

The great sterilizer of men and women, especially the latter, is gonorrhea; the great abortionist is syphilis. And again, these diseases are likely to be acquired by the "fit" among our men, and, unfortunately, often innocently acquired by the "fit" among our women. Therefore, war, pestilence, gonorrhea and syphilis entail an inferior progeny, and hence economically and socially are deplorable.

Most infectious diseases leave the individual less "fit," although after surviving an acute onslaught of some one or more of these diseases he may acquire an immunity to the germs and to infections in general, and he may even, as years go on, transmit more or less of such immunity to his offspring. Or, on the other hand, he may transmit a susceptibility to certain germs to his offspring. Most severe attacks, and even mild attacks, of infection leave permanent marks on the individual, even though he survive. Hence the great purposes of medical men, to-day, are: (1) to prevent disease; (2) to produce anti-vaccines that will protect or cause immunity to a disease without so disturbing the organism as to cause permanent lesions or damage to tissues; (3) if an antivaccine cannot be produced, to discover an anti-toxin that will rapidly inhibit the infection when it occurs; (4) to advance physiology and chemistry so that the needs of a defective organism may be supplied by the organic extract of the knowledge now acquired by the dissemination of diet and food values; (5) to discover the conditions that cause infectious diseases and their prevention.

THE COLON BACILLUS

We harbor, more or less normally, some germs that may become pathogenic, notably the colon bacillus. The part this germ plays in causing acute inflammation or chronic disintegration of organs is variously stated, but it seems ever ready to attack us when our armies of protection are reduced in number or are otherwise engaged. It has been suggested that this germ or its toxins may be a cause of neurasthenia, arteriosclerosis and chronic nephritis, if not of liver disturbances and cerebral disturbances. It has been shown to cause appendicitis, cholecystitis, and perhaps pyelitis. It is thought by some to be a cause of the ever-frequent duodenal and gastric ulcers. It may play an important part in the pernicious anemias, which are now thought to be generally due to an infection. Not infrequently, in acute disease, complications occur which are attributable to the colon bacillus or its toxins. Often some chronic catarrh has been shown to be complicated, if not caused, by infection with the colon bacillus.

Whether there are other normal bacilli in the human body that under certain conditions may become pathogenic has not been discovered, but certain it is that in the prevention of disease we must take into consideration not only the infective but the putrefactive power of the colon bacillus. The prevention of putrefaction in the intestines will promote the immediate health of the individual and may prevent or postpone future organic disease.

Not to discuss the treatment of localized infection from colon bacilli, it may be stated that the treatment of intestinal putrefaction is, unfortunately, unsatisfactory. The prevention of constipation, withholding meat, including fish and poultry, from the diet, the administration of lactic acid bacilli as such or as soured milk, or the administration of yeast, and the cure of any gastro-intestinal inflammation that may be present by proper dietary, medicinal or surgical treatment, may prove very successful for some years in staying or preventing intestinal putrefaction. Although later to be discussed, it may be here urged that healthy teeth and gums are essential factors in the cure of intestinal fermentation.

SLEEP

This is a necessary and not sufficiently discussed part of our daily life. About one-third of each day of an adult's life should be spent in restful, natural sleep. Some individuals require more than others, but eight hours is the average requirement. Loss of consciousness, not syncope, not coma, not stupefaction by drugs, constitutes normal sleep. People who are not mentally alert, who are heavy and stupid or who are mentally insufficient sleep easily. This is true of cretins, of those of low mentality, of the absolutely illiterate (those who have little to think about), and of the very obese (in these cases drowsiness may be due to the amount of blood needed and circulated in the fat). Individuals who are anemic are likely to be sleepy and require more sleep. Children, young children especially, require much more sleep than adults, as their active brains become more readily fatigued.

The conditions favoring normal sleep are probably (1) fatigue products circulating in the brain or causing vasodilatation of the abdominal and peripheral circulation; (2) anemia of the brain more or less relative to that during consciousness, and (3) dimin-

ished cerebral reflex stimulation from external stimuli due to the dulling influence of fatigue products on reflex cerebral or spinal irritability, or it may be that such products circulating in the blood dull the senses and the peripheral sense nerves, or both.

During sleep the pulse is slowed and the brain contains less blood, while the other organs of the body contain more blood. The blood-pressure is lowered. The eliminative glands are more active, notably the sweat glands and the kidneys, but the secreting glands are diminished in activity. During sleep cellular repair takes place, final products of metabolism are formed and excretion is promoted.

Normal sleep cannot be produced by hypnotic drugs, although unconsciousness may be caused and the patient made to sleep. Under the action of hypnotics one or many organs do not functionate and cannot normally act, and the resultant sleep is inferior to natural sleep. Perhaps the most normal hypnotic is that which causes sleep by lowering the blood-pressure and causing anemia of the brain.

High blood-pressure, hysteria, etc., are causes of sleeplessness, and in these and many other conditions sleep must be brought about by physical methods, if possible; or it may be necessary to have recourse to drugs. Absolute insomnia is dangerous and must be stopped, but the continued use of hypnotic drugs invites only disaster, though the temporary use of such drugs may soon promote normal sleep and may actually save life. In fact, not enough thought is given by physicians to the amount of sleep that their patients obtain. Regulation of the sleep should be aimed at by every physician in every case requiring his care.

On the other hand, too much sleep is disastrous; the individual's brain becomes sluggish and incompetent, overpassive congestion of the abdominal organs takes place, sluggish metabolism occurs, constipation, kidney disturbances and a weakened circulation are the results. Patients who complain of being, or whom questioning shows to be, abnormally sleepy are pathologic and need medical advice. Overeating, alcohol, cerebral plethora, obesity, failing circulation and sub-thyroid secretion may all be causes of sleepiness. The cause being discovered, the treatment is self-evident.

Among the most frequent causes of insomnia are peripheral irritations, mental anxiety and hyperthyroid secretion.

WATER

The amount of water that should be taken is important, and quite generally is neglected by physicians in treating their patients. It is not a physiologic crime or a sign of a beginning pathologic condition to arise once at night to urinate (insurance examination blanks to the contrary notwithstanding), in cases in which the patient drinks a glass or two of water before retiring, which is not an infrequent habit. If the emunctories are to properly work during sleep, water is needed, and it should not be withheld. There is no intention in the above to minimize the importance of the symptom of arising several times at night to urinate as an indication of high blood-pressure and kidney, bladder or nervous irritability.

Water in plenty is an essential part of the diet at all times, and especially should goodly amounts of it be ordered in most conditions that require medical treatment. It is absurd to allow the "water cures" to do all of the ordering of this simple sanitary flushing commodity.

Before all operations, if there is time (that is, if it is not an emergency case), large amounts of water as well as plenty of starchy (carbohydrate) food should be given. After an operation the giving of a colon injection of from one pint to one quart of physiologic saline solution is good practice, and if the patient after operation receives such injection he will have less toxemia, less vomiting, better acting skin and kidneys, less headache and more sleep.

On the other hand, let us decry the thoughtless ordering of large amounts of water, or lithiated or other fool water, for patients who may be gouty and have defective kidneys, but who also have impaired circulation. An albuminuria from heart or kidney defect rarely calls for large amounts of water. Excessive amounts will weaken the circulation and cause congestion of the kidneys and dropsies.

The best time for taking extra water, that is, besides the normal goodly amount with meals, is three hours after eating. A considerable amount of water taken with a meal does not diminish or slow digestion; neither does a large amount of water taken between meals diminish the hydrochloric acid of the stomach. Hence water increases and does not inhibit gastric efficiency, and it promotes intestinal health. In cases of gastropnoia or gastric dilatation, large amounts of water may increase distress by overburdening the stomach, which does not readily empty itself.

(To be continued)

New and Nonofficial Remedies

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED BY THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION. THEIR ACCEPTANCE HAS BEEN BASED LARGELY ON EVIDENCE SUPPLIED BY THE MANUFACTURER OR HIS AGENT AND IN PART ON INVESTIGATION MADE BY OR UNDER THE DIRECTION OF THE COUNCIL. CRITICISMS AND CORRECTIONS ARE ASKED FOR TO AID IN THE REVISION OF THE MATTER BEFORE PUBLICATION IN THE BOOK "NEW AND NONOFFICIAL REMEDIES."

THE COUNCIL DESIRES PHYSICIANS TO UNDERSTAND THAT THE ACCEPTANCE OF AN ARTICLE DOES NOT NECESSARILY MEAN A RECOMMENDATION, BUT THAT, SO FAR AS KNOWN, IT COMPLIES WITH THE RULES ADOPTED BY THE COUNCIL.

W. A. PUCKNER, SECRETARY.

HEPCO FLOUR.—Hepco flour is a flour prepared from the Soya bean and has approximately the following composition: protein 42.9; carbohydrate 22.4, of which less than one-half readily yields sugar; fat 20.8; ash 5.1; fiber 4.2; water 4.6.

Actions and Uses.—It is claimed that clinical trials have shown that the carbohydrates in hepco flour are, in the main, not sugar producing and that therefore hepco flour is a suitable food material in cases in which carbohydrates are contra-indicated, as diabetes, amylaceous dyspepsia, etc. It has also been suggested for use in the diet in obesity. The nutritive value of 500 gm. of this flour corresponds to approximately 820 calories due to protein and 900 calories due to fat.

Manufactured by the Waukesha Health Products Company, Waukesha, Wis. No U. S. patent. U. S. trademark applied for.

Hepco Dodgers.—Hepco dodgers is a biscuit prepared from and having approximately the same composition as hepco flour.

Hepco Grits.—Hepco grits is a granulated "breakfast food" made from and having approximately the same composition as hepco flour.

To prepare hepco flour, Soya beans are cleaned and cooked with a little salt, then dried and ground. The flour is sifted and reground. Hepco dodgers are made according to the following recipe: 1½ pounds hepco flour; ½ teaspoonful of salt; mix well and add ¾ cupful of milk and 1 cupful of cold water; 2 eggs which have been thoroughly beaten; beat the whole mixture together into a cooky batter, roll out to ¼ inch thickness, cut with a cooky cutter and bake on well-buttered tins in hot oven. This recipe will make about three dozen dodgers. The dodgers are made up for shipping purposes by having a pure gelatine mixed in with the flour and then rolled out.

Hepco grits made according to the recipe for hepco dodgers. The material is roughly dried out and put through a bread crumber.

THE ETIOLOGY OF PELLAGRA

Recently¹ we discussed the theory put forward by Alessandrini and Scala that drinking-water, because of the presence of silica in colloidal solution, was of consequence in the causation of pellagra. This theory is a novel one in that the relation of silica to the disease had not previously been advanced.

Although pellagra has been known and studied for nearly two centuries, not only is its essential cause unknown, but the broad question whether it is to be classed as a dietary or a communicable (contagious or infectious) disease has never been definitely determined. The spoiled-maize theory has for many years been the favored theory abroad, but its correctness has, for various reasons, been questioned by many. In this country there has arisen, both in the lay and in the medical mind, the opinion that pellagra is to be classed among the infectious diseases. This view has received important support, first, from the Illinois Pellagra Commission² and, more recently, from the Thompson-McFadden Commission³ (Siler, Garrison, and MacNeal).

In a recent issue of the United States *Public Health Reports*, Goldberger⁴ gives a summary of certain work now being done by the United States Public Health Service on the study of pellagra, and advances some most suggestive facts which do not in any way support the infection theory, but strongly point to the belief that pellagra is a disease essentially of dietary origin; that it is brought about in some such way as, for example, by the absence from the diet of essential "vitamins," or possibly, as is suggested by the work of Myers and Voegtlin,⁵ on the presence in vegetable foods of excessive amounts of a substance such as soluble aluminum salts. Goldberger states that a

large series of monkey inoculations were begun a year ago by Lavinder, Francis and Lorenz at the Marine Hospital in Savannah and that, although over one hundred animals were inoculated in every conceivable way and with practically every tissue, secretion and excretion from patients in a number of grave and fatal cases, the results up to the present have been negative.

A study by Willets of the records of the Georgia State Sanitarium showed that of 996 patients admitted during 1910, excluding those who died, were discharged during their first year, or had pellagra on admission or within a year of admission, there remained at the institution after one year, 418. Of this number, 32 or 7.65 per cent. have developed pellagra since that time. Of the present employees at the asylum, 293 have been in more or less intimate association with pellagrins and have lived in substantially the same or in identical environment for at least one year. Had pellagra developed among these employees at the same rate as it did among the inmates, 22 of them should have developed the disease. As a matter of fact, not one has done so.

The studies at the orphanage at Jackson by Waring show that on July 1, 1914, of 211 inmates, 68 or 32 per cent. had pellagra. A study of the distribution of these cases with respect to age brought out the remarkable fact that practically all the cases were in children between the ages of 6 and 12 years, of whom over 52 per cent. were affected. In the group of 25 children under 6 years of age there were 2 cases and in the group of 66 children over 12 years old there was but one case. The author states that inasmuch as all the children live under identical conditions as to environment, the remarkable exemption of the group of children under 6 and over 12 years of age is no more understandable on the basis of an infection than is the absolute immunity of the employees at the Georgia State Sanitarium.

A searching inquiry was made at both institutions covering all conceivable factors that might possibly explain the striking exemption of the groups referred to and the only constant difference discovered related exclusively to diet. It was found that at both institutions those of the exempt groups were found to subsist on a better diet than those of the affected groups. In the diet of those developing pellagra there was noted a disproportionately small amount of meat or other animal protein food; and the vegetable component, in which corn and syrup were prominent and the legumes relatively inconspicuous elements, formed a disproportionately large part of the ration. Other than this gross defect, no fault in the diet was appreciable and the author believes that the evidence clearly points to it as the cause of the pellagra at the two institutions.

In this connection it is of interest to note that the Illinois Pellagra Commission² in their report state that the total population of the Peoria State Hospital dur-

5. Myers, C. N., and Voegtlin, Carl: Soluble Aluminum Compounds. Their Occurrence in Certain Vegetable Products, Pub. Health Rep., June 19, 1914, p. 1625.

ing the epidemic of 1909 was about 2,100 and of these there were at least 8.4 per cent. with pellagra. Yet during that period none of the employees suffered from the disease, in spite of the fact that they were exposed fully as much to the bites of insects and drew their food and water-supplies from exactly the same sources as the patients. "This freedom from pellagra on the part of the physicians, nurses, attendants and other employees has been absolute in all of the institutions." That Commission found that most of the patients with pellagra belonged to the chronic insane composed of "the defectives, senile demented, epileptics and the terminal stages of dementia praecox."

Goldberger believes that the deteriorated mental condition, causing apathy and indifference, results in an eccentricity in the diet and that this, in conjunction with a diet admittedly low in animal protein components, explains the excessive prevalence of the disease at the Peoria institution, a hospital almost all of whose inmates in 1909 were of the hopeless, incurable class drawn from the other Illinois institutions.

THE DISTRIBUTION OF UREA IN THE BODY

It requires no argument to establish the importance which urea has in the chemistry of the living body. Any substance which is formed in the organism to the extent of 30 gm. or more a day, and which is ordinarily excreted with extreme promptness, deserves consideration as a product which needs to be handled appropriately by the normally functioning individual and as a possible factor of danger in disease. Despite the abundance of information regarding the occurrence of urea and its antecedents in the body, it is surprising that so little quantitative information has been available with respect to its distribution in the blood and tissues. The explanation for the paucity of data of this sort is doubtless to be found in the lack of easily applied methods of analytic study applicable to this nitrogenous excretory product. The introduction of the urease method¹ of measuring the content of urea has furnished a peculiarly suitable procedure for ascertaining something further about the distribution of urea under various conditions of health and disease. By the use of this method in the laboratories of the Johns Hopkins Medical School Drs. Marshall and Davis² have secured valuable statistics in this field.

Hitherto there has been a widespread belief that the genesis of urea is restricted to special organs, among which the liver has been assumed to exercise a dominant rôle. That other parts of the body are not without significance in urea formation could no longer be denied when it was found that this substance continued to be excreted in not inconsiderable quantities after

more or less complete exclusion of the liver in experimental animals. In such cases the muscles have been assumed to play a dominating part. The newest investigations, on the other hand, have proved more conclusively than ever that urea occurs in all of the organs and tissues of the body. More significant than this wide-spread distribution, however, is the fact that it occurs throughout the body in approximately uniform concentration. This is true both in normal conditions and in cases in which, owing to such interference with excretion, an abnormally large amount of urea is present. An exception to the rule is found in the case of fat. This fact, however, is not surprising in view of the well-known slight solubility of urea in fats and the added fact that only relatively small amounts of water are present in adipose tissue. The somewhat higher content of urea found in the kidneys and other parts of the urinary tract is readily understood as the result of the unavoidable contamination of these organs with urine.

The approximately uniform distribution of urea throughout the body is also found when the urea content has been increased either by injections of urea or by interference with excretion by the kidneys, or by both means. The body cells appear to be able to take up surprisingly large quantities of the substance. The diffusion of urea to all parts of the body is accomplished very quickly. For example, no matter how soon blood is withdrawn after the end of an injection of urea a large part of this nitrogenous material has already gone out of the circulation. In view of this fact it is not difficult to understand why the concentration in the blood is never essentially higher or lower than that in the tissues themselves. Furthermore, urea is eliminated with extreme rapidity by the kidneys. The rate of excretion in normal animals is directly proportional to the concentration of urea in the blood. It may be retarded, however, after a certain amount of dehydration has occurred, that is, when elimination cannot be accomplished owing to lack of water for the kidneys to secrete. If water is then given, urea is again thrown out at an increased rate. There are doubtless few, if any, substances with which the body cells come in contact that permeate all kinds of cells so readily and that are eliminated so easily as is urea. As Marshall and Davis have pointed out, it is clearly the most desirable form into which nitrogen could be put for elimination from the body.

When the excretion of urea is prevented, either experimentally or by disease in the case of nephritics, the entire amount formed is stored in the body with the exception of small amounts secreted in the bile, sweat, etc. Here, again, its distribution is very general and uniform. No evidence whatever has been obtained of the possible transformation of urea into other substances in the body. This fact, taken in connection with the ease with which urea is distributed, excreted, or stored up as the case may be, is not without signifi-

1. Marshall, Jr., E. K.: A Rapid Clinical Method for the Estimation of Urea in Urine, *Jour. Biol. Chem.*, 1913, xiv, 283; A New Method for the Determination of Urea in Blood, *ibid.*, xv, 487.
2. Marshall, Jr., E. K., and Davis, D. M.: Urea: Its Distribution in and Elimination from the Body, *Jour. Biol. Chem.*, 1914, xviii, 53.

cance in relation to the symptoms observed in uremia. The chemical and physiologic properties of urea are such that it ought to be a non-toxic substance and the newer experiments show it to be non-toxic in any moderate or fairly large amounts. Only when introduced in enormous doses so that it approaches a concentration of 1 per cent. of the tissues in general does it produce a fatal effect. For this reason the Baltimore investigators conclude that it is improbable that urea is the only toxic agent in uremia, as has been supposed by some writers, although it may take some share in producing the symptoms of this condition.

The foregoing observations illustrate how greatly our knowledge of the chemistry of the organism is advanced when quantitative methods can be brought to bear on its problems. For additional illustrations one need only refer to the great advances which have been made in recent months in following the distribution of other so-called catabolites, such as creatin, creatinin, uric acid, and the amino-acids, in the blood and tissues. Indeed, blood and tissue analyses have emerged into new prominence in the laboratory. It is surprising to realize that until this period, the extent to which urea may be stored in the tissues has never been accurately determined. The newer researches have served to clear up many earlier conflicting and unsatisfactory data. They have demonstrated that retention of urea is a regular occurrence in certain cases of severe nephritis, and that the amount of urea in the blood does not account for the amount theoretically present in the organism. Finally, they have furnished evidence of an increase in the urea content of tissues in cases in which the blood urea is abnormally high. Contributions of this sort are certain to help clear up the pathology of conditions like uremia before long.

EARLY HUMAN REMAINS IN AMERICA

The determination of the age of the earliest human remains found on the American continent is of great interest. Until a few years ago North America was supposed to offer the most valuable evidence in this regard, though the Bureau of American Ethnology declared in 1907 that "no specimen had come to light in the northern continent which from the standpoint of physical anthropology represented other than relatively modern man." At that time some "apparently epoch-making discoveries" were reported from the Lagoa Santa Caves of Brazil, together with numerous finds of bones and cultural objects in Argentina. As a result the attention of the world was attracted to these places and there was a renewal of the story of Atlantis, the origin and descent of the human race being traced from very primitive anthropoid forms of South America. More recently interest has reverted to North America from the discovery of human remains in an asphalt deposit at Rancho La Brea in Southern California. A preliminary report on these

was read before the Museum of History, Science and Art of Los Angeles, June 11, 1914, by John C. Merriam.¹

The Bureau of American Ethnology was so much interested in the South American finds that two experts were sent to conduct an impartial investigation into the scientific significance of the discovered objects. Dr. Ales Hrdlicka went as the anthropologist and Mr. Bailey Willis of the United States Geological Survey as geologist. The material brought home from the various beds by the Hrdlicka-Willis expedition was submitted to the paleontologist of the United States Geological Survey and to the Geophysical Laboratory of the Carnegie Institution of Washington for an exhaustive investigation of their physical character and conditions of origin. Almost needless to say, the scientific criteria determined on were thorough and such as were calculated to the best possible degree to secure reliable results.

The conclusion was, "It seems quite evident that the human remains from the Lagoa Santa Caves cannot be accepted without further and more conclusive proofs as belonging to a race which lived contemporaneously with the extinct species of animals found in the same caves; and there is no reliable foundation for the remainder of the data relating to the specimens on which geologic antiquity can be based."

A similar unfavorable conclusion was reached regarding the antiquity of the skull taken from the harbor of Buenos Ayres. On this was based the theory of *Diprothomo platensis*, so called from the River Platte, in which the skull was found. The specimen had been taken from the oozy bed of the river when the workmen were excavating a rudder pit for the dry dock at Buenos Ayres. In geologic age, according to Professor Ameghino who wrote about it, it was a remnant from the Lower Pliocene and had originally belonged to a second or premediate precursor of man as part of his brainpan. He asserted that as to conformation it was older and less developed than the famous Neanderthal skull. Careful examination, however, showed that the facial angle is practically the same as in the average Indian. Dr. Hrdlicka says, "The Buenos Ayres skull fragment fails utterly to reveal any evidence which would justify its classification as a representative of a species of ancient primates, premediate forerunners of the human being, the *Diprothomo*. Every feature shows it to be a portion of the skull of man himself; it bears no evidence even of having belonged to an early or physically primitive man, but to a well-developed and physically modern-like individual."

Mr. Bailey Willis, the geologist of the North American expedition, after a careful investigation of the circumstances of the find and an examination of the character of the river bank, finds that he can give no

1. Merriam, John C.: Science, Aug. 7, 1914.

weight to the theory that "the unknown workman who found the skull and gave it to the foreman really dug it out of undisturbed ancient pampayan." The question of provenience is the crux of the whole matter of determining the age. It is this question also that has arisen with regard to the Rancho La Brea discoveries, that is, whether the materials existed originally in the associations in which they were subsequently found. In asphalt chimneys or tar pits such as are now being excavated at Rancho La Brea, materials may and indeed almost necessarily do move in the course of time, and their present associations do not necessarily determine their age. Objects of very different ages may have drifted together by gravity in the viscous material in which they lie buried.

The conclusion of the preliminary report, then, is that, while it is not possible to give a definite estimate of the age of the skeleton found, it belongs to a distinctly modern stage of evolution. It does not necessarily belong to the present historical period, but cannot be considered as having antedated it by many thousands of years. Merriam considers it well worth exhaustive scientific investigation, and the last word on the subject cannot be written until a great deal more study has been given the objects found. The associations are with specimens distinctly later in age than the typical Rancho La Brea fauna, which come from a very old geologic period. According to Dr. A. L. Kroeger, the racial characteristics do not differ decidedly from those of persons whose remains have been excavated in mounds on Santa Rosa Island off the coast of Southern California. While the question of antiquity is undecided, every evidence which we have would seem to point in North as well as South America to the comparatively recent origin or occurrence, geologically speaking, of man on our continent.

RESUSCITATION FROM MINE GASES

The Report of the Committee on Resuscitation from Mine Gases, appointed by the Council on Health and Public Instruction of the American Medical Association at the request of the Bureau of Mines of the Department of the Interior, has just been published by the Bureau.¹ This commission, which grew out of the work of the Joint Committee on Resuscitation from Electrical Shock, appointed by the Council from the Fellows of the American Medical Association, the National Electric Light Association and the American Institute of Electrical Engineers, consists of Dr. Walter B. Cannon, Chairman, Professor of Physiology, Harvard University; Dr. George W. Crile, Cleveland; Dr. Joseph Erlanger, Professor of Physiology, Washington University, St. Louis; Dr. Yandell

Henderson, Professor of Physiology, Yale University, and Dr. S. J. Meltzer of the Rockefeller Institute for Medical Research. This committee was requested by the director of the Bureau of Mines to carry on investigations for the development of an efficient method of resuscitation which may be administered by miners and other persons who have not had medical training, but who frequently have the opportunity to treat fellow workmen overcome by mine gases in places, generally in mines, that a physician or surgeon cannot reach in time to save life.

The committee reports that it has visited mines in the bituminous and anthracite coal regions of Pennsylvania, has met and talked with men of wide practical experience, witnessed demonstrations of artificial respiration by different methods and examined them critically, studied all the available mechanical devices for maintaining breathing and carried on a considerable amount of experimental investigation into the best methods of resuscitation following the inspiration of mine gases.

The report reviews the physiology and pathology of carbon monoxid poisoning, discusses the Sylvester and Schäfer methods of artificial respiration and, following the course laid out in the previous report on resuscitation from electrical shock, strongly recommends the Schäfer method on account of greater simplicity and ease of performance, absence of trouble from the tongue blocking the air passage, lessened danger of injuring the liver or breaking the ribs and larger ventilation of the lungs. The first three of these advantages were apparent. On the fourth point, larger ventilation, the commission instituted a series of experiments both on men and animals which convinced the committee that the prone pressure method of Schäfer is the most effective means of artificial respiration. Regarding the mechanical devices, four machines are now on the market, the Draeger pulmotor, the Dr. Brat apparatus, the lung motor and the Salvator. The pulmotor and the Dr. Brat apparatus were investigated and tested by the committee and were disapproved. It was found that "repeated suction of air from the lungs is not physiologic and if continued, is apt to result in injury to the lungs and inadequate inflation." In connection with the experiments of the commission on mechanical appliances, Dr. Meltzer has devised an apparatus which is easily and quickly applied and which the committee recommends on account of its certain action, the freedom from suction in expiration, and its lightness, cheapness and simplicity. A description of the apparatus and directions for its construction are contained in the pamphlet. This apparatus has already been described by Dr. Meltzer in *THE JOURNAL*.²

Summing up its experience and findings, the committee recommends artificial respiration in all cases of

1. The report is designated Technical Paper No. 77, and can be obtained by sending 5 cents to the Superintendent of Documents, Government Printing Office, Washington, D. C. It should be obtained by all interested in this subject.

2. Meltzer, S. J.: Simple Devices for Effective Artificial Respiration in Emergencies, *THE JOURNAL A. M. A.*, May 10, 1913, p. 1407.

gas poisoning and, as mechanical devices are seldom at hand, manual methods are recommended for first aid. Of these the prone pressure method is recommended unless the patient is suffering from some local wound which makes this impossible, in which case the Sylvester method may be substituted. In all cases of carbon monoxid poisoning, oxygen should be given instead of air. If the victim is still breathing spontaneously, oxygen may be given by fastening to the face a mask provided with outlet valve and an inlet valve, connected with a bag provided with oxygen from a cylinder. The Meltzer apparatus is recommended as the best of the mechanical devices available.

This report together with the report on resuscitation from electrical shock are notable and valuable contributions to our practical and scientific knowledge of the causes, conditions and treatment of these industrial accidents. The *Electrical World* at the time the report of the Committee on Resuscitation from Electrical Shock was published, reprinted this report in large quantities and distributed them with the accompanying chart, to electrical plants, power-houses and stations all over the country. They have been translated into a number of foreign languages and are recognized as standard and authoritative monographs on this subject. The report of the Committee on Resuscitation from Mine Gases is equally valuable and worthy of a similar wide-spread distribution. The work done by the members of these two commissions is a credit to the medical profession and the Association which they represent.

WORK FOR THE SAKE OF HEALTH

Extensive alterations in the social and industrial conditions of large groups of individuals almost always incidentally bring about changes in their hygienic situation. As a general rule, when the changes are in the direction of what we regard as social betterment the conditions of living are improved, sanitation is cultivated in greater measure, and the promotion and preservation of health follows as a natural consequence. A study of such movements reveals the advantages, from the point of view of both public and personal hygiene, that have followed the pure food crusades, the campaign against alcoholism, child-welfare innovations, investigations of institutional management, regulation of industrial conditions in respect to hours of work, factory inspection, etc.

There are, strange as it may seem at first thought, certain modern industrial changes which carry with them detrimental features that are not apparent on the surface. A growing group among whom the amount of muscular work done is small in comparison with the daily activities of their ancestors is coming into existence. We are not referring here to

the fact that shorter hours of work have everywhere become the custom—that the blacksmith who formerly toiled twelve hours now completes his working day in eight hours. The changes which we have in mind here are a consequence of altered methods of conducting business with the modern extension of commerce. Machinery has replaced muscle. The development of the industries by machinery has called for a different type of human working-power in which skill rather than strength is required. As a modern writer¹ has expressed it, the bodily qualities of the worker have been forced by the employer more and more into the background of valuation. Industrial factory work requires not so much strong men as persons who can perform with skill the many small tasks which the machines have so far not been able to perform. Hence the tendency to employ children, half-grown persons and women.

More significant than this is the fact that the number of those who do little manual labor has increased greatly. This is an era of office workers, of business and governmental officials whose implements are the desk chair, pen and pencil, rather than the hammer and the hoe. Even in agriculture machinery has eliminated some of the hardest types of manual labor. Muscular exercise, however, is a benefit rather than a detriment to the human economy. It improves the function of the essential organs of the body. Hence there has arisen an unexpected consequence, namely, the habit of trying to avert the possible harmfulness of some of these changed conditions by "balancing the lack of paid muscle work by work for hygienic reasons, by play and sport." The creation of work for the sake of health sounds almost paradoxical.

Current Comment

"LARGE" AND "SMALL" MEDICAL COLLEGES

The application to medical colleges of the terms "large" and "small" should and usually does depend on the size of the classes enrolled. With this understanding it can be stated that there are some small medical colleges which are admirably equipped and which are undoubtedly furnishing their students with an excellent scientific and practical medical training. In proportion to the numbers of students enrolled, some of these small colleges are among the best equipped institutions in the country, and some of them have been rated in Classes A+ and A by the Council on Medical Education. No one of these satisfactory small colleges, however, is "notoriously lacking in equipment" as implied in an editorial comment in one of our monthly exchanges. There are, indeed, several small medical colleges which are "notoriously lacking in equipment," but in no instance does such a

1. Rubner, M.: Address on the Nutrition of the People, delivered before the Fifteenth International Congress on Hygiene and Demography, at Washington, Sept. 24, 1912, and published in the Transactions.

school furnish a satisfactory training in medicine. At the other extreme, there are some medical colleges which have large enrolments of students, out of all proportion to the limited supply of expert teachers, laboratory equipment and clinical facilities. Because of these deficiencies or because of a too liberal administration of entrance standards, such schools do not and cannot furnish a satisfactory training. Some of these medical schools with large enrolments, for good reasons, are rated in Classes B and C by the Council on Medical Education. A reference to state board statistics, furthermore, shows that the graduates of some of these "large" medical schools do make poor records in the licensing examinations. It should not be said, however, that "as a rule the larger the college the higher is the percentage of its graduates who fail before the state examining boards" as stated in the editorial referred to. No such statement, meanwhile, is made in the State Board Number of *THE JOURNAL*,¹ to which the editorial refers, nor does any statement appear which would give such an impression. In the State Board Number it is stated that "the mere fact that a college has large classes is no indication that it furnishes a better medical training."² It is also true that "the larger the college . . . the more serious is inferior teaching."³ But these statements do not imply, nor should they be interpreted to mean, that in all colleges having large classes the teaching is inferior, or that all of them have large percentages of their graduates fail before state licensing boards. On the contrary, there are several colleges having large enrolments which at the same time have excellent supervision and, in proportion to their students, have an ample supply of expert teachers and an abundance of laboratory equipment and clinical facilities. Some of these large colleges, in fact, furnish an excellent medical training and their graduates make excellent records before state licensing boards. We would emphasize that a medical college should not be judged by the number of students enrolled but by the qualifications of its teachers; the possession of suitable and well-equipped laboratories; the abundance of clinical facilities available; the supervision exercised over the work and welfare of its students and—last but not least—the evidences of the skill and training of its graduates.

THE SIGNIFICANCE OF THE WORD LUTEIN

The word "lutein" has long been applied in physiologic chemistry to designate a group of fat-coloring matters which occur in nature and which have more recently often received the general designation of lipochromes. These yellow pigments are found in the adipose tissue, in the serum of the blood, in serous fluids, in fatty structures of the retina, in the egg-yolk, and in the corpora lutea. The use of the term "lutein" has been restricted as a rule to the yellow coloring-matter which develops in these ovarian structures, although one can find the word applied to derivatives of other physiologic tissues as synonymous

with lipochrome.⁴ Thus in a recent discussion respecting the appearance of a yellow pigment in cerebrospinal fluid in cases of tumor of the spinal cord the word "lutein" is employed to designate the color.² Hitherto the chemistry of this group of compounds has been very indefinite and they have been classified and identified by their solubilities and other physical properties. Now that the subject is receiving more serious study, however, and the precise nature and relationships of the lipochromes or luteins is being cleared up,³ it may soon be possible to speak accurately of carotin or xanthophyll or some other specific substance instead of applying the more indefinite group expressions referred to above. It therefore seems particularly unfortunate at this time to find the word "lutein" entering anew into the nomenclature of medicine in an entirely different sense. Lately various preparations of desiccated corpora lutea from animals are being sold under the designation of lutein.⁴ This new therapeutic product obviously represents something more than merely the yellow pigment of a part of the ovarian structure, for there is no evidence that the lipochrome itself is responsible for any physiologic effects. Evidently the word "lutein" has commended itself, without consideration of the historical import of the word, as a euphonious designation which would at once suggest the natural origin of the product. This is not an isolated instance of confusion of terms. The word "bromalin" has been devised by manufacturers for a synthetic bromin derivative despite the existence of the word "bromelin," the name of the proteolytic enzyme of the pineapple. Other instances might be cited. We trust that a reference to the matter here may help to avert further undesirable unnecessary complication of this sort on the part of those who are devising names for new products.

PUBLIC HEALTH IN INDIANA

Health administration in Indiana has for a long time past been vigorous and energetic, as it is in many of our other states. It has also been unique, peculiarly up-to-date and popular in its methods of attracting attention and affording instruction. The latest activity of the health forces of the state is thoroughly characteristic. Governor Ralston has issued a proclamation designating Friday, Oct. 2, 1914, as Disease Prevention Day. He urges the cities and towns throughout the state to make special arrangements for appropriate exercises, emphasizing the importance of public health, and the joint responsibility of all citizens therefor in order to inspire in them a desire to cooperate in all sane efforts for the prevention of physical diseases. The state board of health has prepared a special bulletin containing a copy of the governor's proclamation and suggestions for the celebration of Disease Prevention Day in the towns of Indi-

State Society to Meet.—The Minnesota State Medical Association will hold its annual meeting at the St. Paul Hotel, St. Paul, October 1 and 2, under the presidency of Dr. Alfred E. Spaulding, Luverne.

Urges County Health Organization.—Dr. H. W. Hill, executive secretary of the Minnesota Public Health Association, proposes the organization of a health association in each county of the state.—County health organizations have already been formed in Wilmar and Marshall counties.

Advance in Work against Tuberculosis.—The first annual report made by Dr. Robinson Bosworth, executive secretary of the advisory commission of Minnesota State Sanatorium, gives an interesting summary of the progress of the work of establishing county tuberculosis sanatoriums. Nopeming Sanatorium, St. Louis County, 14 miles from Duluth, is under operation with sixty patients; Ottetail County Sanatorium at Battle Lake, with sixty-five patients; Nopeming County Sanatorium has been enlarged by the addition of an infirmary of thirty-five beds, a heating plant and laundry, at an expense of \$75,000; Ramsey County Tuberculosis Pavilion is open this month with a capacity of 110 patients; Hennepin County is constructing a seventy-five bed institution at Glen Lake near Hopkins, which will be completed within a year at a cost of about \$100,000; Lincoln, Lyon, Pipestone, Murray, Cottonwood, Rock, Nobles and Jackson counties have organized a sanatorium district and are seeking a suitable location for the joint sanatorium on which about \$95,000 will be expended; Yellow Medicine, Chippeway and Renville counties have voted to build a joint sanatorium providing a fourth enters the group. Lac Qui Parle is the fourth county of this group; Wabasha County has requested the commission to choose its selected site; Douglas County has made a tax levy to build a sanatorium and is endeavoring to get Grant, Pope and Stevens counties to join with it; the county board of Blue Earth County is leaving the matter of a sanatorium to the wishes of the people at an election; Brown and Nicollet counties are ready to build a sanatorium, and Redwood and Watson counties wish to join this group; Goodhue County has accepted plans for a building to be erected on the Cannon Falls site; Pope and Norman counties have purchased a sanatorium site at Crookston; Clay and Becker counties have selected a location at Lake Park and have appointed an architect; Beltrami, Koochiching and Hubbard counties have voted their tax levies, appointed sanatorium commissions and will build at or near Bemidji; Marshall County, either alone or with Pennington County, will build a sanatorium; Wadena and Todd counties have made the necessary levy and are endeavoring to secure a third county for the group. The expenses of the advisory commission for the year were \$9,456.93, leaving a balance in hand of \$543.07.

MISSISSIPPI

Pellagra Not Admitted to Vicksburg.—The trustees of the Vicksburg Emergency Hospital have passed a resolution to accept no pellagra cases for treatment on the ground that the hospital has no facilities for the proper treatment of such cases. The railroads have been notified not to bring pellagra patients into Vicksburg, but protest that they have no means of diagnosing the disease.

Malaria in Washington County.—In response to the request made to the surgeon-general of the Public Health Service that antimalarial work be undertaken at Greenville and large plantations nearby, Surgeon Rudolph H. Von Ezdorf, Assistant Surgeon Robert C. Derivaux and Sanitary Engineer J. A. Lee Prince, U. S. P. H. S., have been detailed to make an investigation of the conditions contributing to the spread of malaria in that region.

New Society Organized.—The Homochitto Valley Medical Society was organized in Natchez, September 8. The districts include Adams, Amite, Franklin, Jefferson and Wilkinson counties, and the following officers were elected: president, Dr. Richard D. Sessions, Natchez; county vice-presidents, Adams County, Dr. Joseph D. Shields, Pine Ridge; Amite County, Dr. William R. Brumfield, Gloster; Franklin County, Dr. George T. Warren, Bude; Jefferson County, Dr. Leon R. Harrison, Fayette; and Wilkinson County, Dr. Columbus L. Field, Centerville; secretary-treasurer, Dr. Marcus Beckman, Natchez.

NEW JERSEY

New Officers.—Morris County Medical Society at Morris Planes, September 8: president, Dr. Frederick E. Knowles, Boonton; secretary, Dr. Henry W. Kice, Wharton.

Addition to Insane Hospital.—Plans have been adopted for an addition to the Overbrook Hospital for the Insane, Verona. The new building will have accommodations for 270 patients.

Measures against Anthrax and Glanders.—The State Board of Health, September 8, adopted regulations designed to prevent the importation of anthrax from Delaware, where cattle are said to be infected nearly every year.—The New Jersey State Health Department is securing from the Bureau of Animal Industry at Washington and forwarding to local boards of health throughout the state quantities of mallein to be used for the ophthalmic test on horses.

NEW YORK

Infantile Paralysis.—Cases of infantile paralysis are reported from Syracuse and Binghamton. The State Department of Health is taking every precaution to prevent the spread of the disease.

Personal.—Dr. Alexander Lowenstein has been placed in charge of the work of the Jewish Philanthropic Society recently organized at Rochester.—Dr. Harold H. Fox, Springville, has been appointed medical adviser of Cornell University and assumed charge of his new office at Ithaca, September 20.—Dr. Wardner D. Ayer, Rensselaer, has been appointed pathologist to the Crouse-Irving University, Syracuse.—Dr. and Mrs. Francis R. Benham, Syracuse, have returned from abroad.

New York City

Personal.—Dr. and Mrs. John J. Moorhead and Dr. and Mrs. George Draper have returned from Europe.—Dr. Michael J. Thornton, for four years in charge of the psychopathic ward of Bellevue Hospital, has been appointed chief of staff of the psychopathic ward of the Kings County Hospital, Brooklyn, succeeding the late Dr. William B. Moseley.

Typhoid Epidemic in Brooklyn.—Up to September 12 there have been fifty-three cases of typhoid fever reported from the Park Slope section of Brooklyn, but since that time no new cases have been reported. The source of the infection has not been determined, and though many specimens of water have been examined, there is no indication thus far that the trouble lies in the water-supply.

New Requirement for Peddler's License.—The Department of Health and the Department of Licenses have determined to extend the scope of the medical examination now made of applicants for peddler's licenses and to include in each instance a Wassermann test. The physical examinations will be made in the tuberculosis clinics at present. Licenses will be denied to tuberculous persons whose sputum shows the presence of the tubercle bacilli and to those whose blood gives a double plus Wassermann reaction.

NORTH CAROLINA

New Hospital.—The construction work on St. Luke's Hospital, Newbern, being built by Drs. R. Duval Jones and Joseph F. Patterson is progressing rapidly and it is expected that the hospital will be opened before the end of the year.

Trachoma Investigation.—Dr. A. D. Foster of the United States Public Health Service, in his trachoma investigation in this state, has visited seventy-one white and thirteen colored schools, examining over 12,000 pupils and finding about thirty-cases of trachoma. The heaviest infection (eighteen cases) was found among the 207 pupils examined at the Indian school at Cherokee, Swain County; but this was also the only place where measures had been taken to determine the presence of the disease and to control its spread. The heaviest infection among whites was in Caldwell County, lighter infections being found in Cherokee and Mitchell counties. Only one negro was found infected. Dr. Foster believes that foreign immigration has played little or no part in introducing the disease here.

State Board Prizes.—The State Board of Health has offered six prizes of \$25 each for the best articles on six health subjects written by citizens of the state. The subjects of the articles are, typhoid fever, malarial fever, diphtheria, scarlet fever, whooping-cough and measles. The prize essays will be published in the *Bulletin of the State Board of Health*. The contest is open to any citizen of North Carolina, who may compete for any or all of the prizes. The articles must be within one thousand to two thousand words, and the last day for filing the manuscripts for the competition will be, for typhoid fever, October 1; malarial fever, November 1; diphtheria, December 1; scarlet fever, Jan. 1, 1915; whooping-

cough, February 1, and measles, March 1. The judges of the competition will be the editor of the *Bulletin*, an editor of a city newspaper, a physician and a layman.

OHIO

New Hospital.—Plans have been completed for a new Jewish hospital, Cleveland, and construction is to begin October 15.

Protest Recognized.—The Logan County Medical Society, which protested its transference by the council of the State Medical Society to the Dayton district, has been retransferred to its old district, known as the northwestern district.

"Baby's Health Is Cleveland's Wealth."—This is the slogan adopted by the child hygienic committee of Cleveland for "Baby Sunday," September 13. Every minister was requested to use the baby campaign as a theme for his sermon on that day. Lectures and exhibitions were given at the City Hall on September 14, and department stores also gave special window demonstrations on that day.

Citizens' Hospital for Barberton.—A very successful campaign to raise money for a hospital has just been terminated in Barberton. The hospital is to have a capacity of fifty beds, and \$50,000 was raised. Over five thousand of the citizens own stock in the hospital, and it is to be known as the Citizens' Hospital Company. The hospital is to be self-supporting, and its equipment will be modern in every respect.

Small-Pox.—Small-pox continues to prevail in certain districts. The board of health of Sandusky is making a vigorous effort to rid that city of an outbreak which has lingered for some time. A meeting of all Sandusky physicians was called on September 9, and they were addressed by Dr. Frank G. Boudreau of the State Board of Health on the diagnosis and control of the present mild outbreak of small-pox. Dr. Boudreau afterward examined the Sandusky cases, of which there are three at the present time.

Director of Bureau of Juvenile Research Appointed.—Dr. Thomas H. Haines has been appointed chief psychologist of the new juvenile research bureau under the direction of the Ohio State Board of Administration. The position now occupied by Dr. Haines is an extremely important one, because of the large number of institutions under the care of the Ohio State Board of Administration. The new bureau will probably be located on the Ohio State University campus as a part of the proposed medical group.

Personal.—Dr. Charles H. Clark, superintendent of the Newburg State Hospital, Cleveland, has been appointed superintendent of the Lima State Hospital for the Criminal Insane. The new hospital is practically completed and will pass under the control of the State Board of Administration early in 1915.—Dr. Julius J. Buel, wife and daughter, Cleveland, have returned from abroad.—Dr. and Mrs. John J. R. MacLeod, will sail for home, September 19.—Dr. and Mrs. John Edwin Brown and son, Columbus, have returned from Europe.

District Health Officers for Ohio.—A bill to divide the state into health districts and to provide for whole-time, experienced district health officers, will be introduced at the next session of the general assembly. Each district will comprise one or more counties, and the county commissioners will act as a board of control. Only persons who have the degree of M.D., D.P.H., or some equivalent degree, will be eligible as candidates for the position of district health officers. All candidates will have to pass a civil service examination. The minimum salary is fixed at \$2,000. In addition to the duties now performed by health officers and boards of health, the district health officer will be required to provide for medical inspection of schoolchildren, the inspection of workshops, factories and a complete system of milk and dairy inspection. District health officers will have jurisdiction everywhere except in incorporated cities.

OREGON

State Association Meeting.—The annual meeting of the Oregon State Medical Association was held in Portland, September 10 and 11, and the following officers were elected: president, Dr. Alpha E. Rockey, Portland; vice-presidents, Drs. Robert J. Pilkington, Astoria; William H. Dale, Harrisburg, and Robert J. Marsh, Portland; secretary, Dr. Marius B. Marcellus, Portland (reelected); treasurer, Dr. Katherine C. Manion, Portland (reelected); councillors, Drs. Joseph A. Pettit and Calvin S. White, Portland, and Francis G. Swedenburg, Ashland; delegate to the American Medical Association, Dr. Walter T. Williamson, Portland, and alternate, Dr. Kenneth A. J. Mackenzie, Portland.

PENNSYLVANIA

Diphtheria Epidemic.—A rather serious epidemic of diphtheria at Keystone Mines is under investigation by the State Health Department.

Leprosy in Wilkes-Barre.—The health authorities of Wilkes-Barre have been advised that Joseph Norman of that city, who went to Philadelphia recently, is suffering from tubercular leprosy. The house in which this man lived has been placed under quarantine.

Diarrheal Epidemic in the Coal Regions.—An epidemic of acute diarrhea has been reported from Freeland, Jeddo, Upper Lehigh, Feltley, Drifton and surrounding towns. Dr. Charles J. Hunt of the State Health Department, sent to the Luzerne coal regions to investigate the epidemic, reports September 1 that 1,000 cases have been found. An investigation of the cause is under way.

Philadelphia

Leptous Rats.—Two rats infected with leprosy germs have been discovered by the Department of Health in its campaign to clean the river front. The first rat with traces of leprosy was brought to the receiving station at Race Street pier, three weeks ago. The second, caught September 17, was found in a building near the wharf.

Personal.—Dr. Harry Lowenburg has returned from abroad.—Dr. and Mrs. G. Oram Ring have returned from the Mediterranean.—Dr. Laura Hunt has been appointed Professor of Otology at the Women's Medical College, to fill the position left by the death of Dr. Emma Musson.

New Ward Equipped.—A new ward for men and another for children has been equipped at the College Hospital, according to an announcement made at the opening exercises of the Woman's Medical College. The children's ward has been equipped largely by private donations, through the efforts of Dr. Theodore LeBoutillier and others.

WISCONSIN

Home from Europe.—Drs. Albert A. Maurer, La Crosse, and Frederick A. Kraft, Milwaukee, have returned from abroad.

Bacteriologist Appointed.—Miss Anna Stolzenfeld, as the result of a civil service examination, has been made first assistant bacteriologist in the Municipal Laboratory, Milwaukee.

New Officers.—Second District Medical Association at Lake Geneva, Wis., September 1: president, Dr. Gustave Windesheim, Kenosha; secretary, Dr. Milton V. Dewire, Sharon (reelected).

GENERAL

Life Insurance Directors Meet.—The annual meeting of the Medical Section of the American Life Convention will be held in Dallas, Texas, October 7.

Military Surgeons to Meet.—The twenty-third annual meeting of the Association of Military Surgeons of the United States will be held in Cincinnati, September 29 to October 2, with headquarters at Hotel Gibson.

Railway Surgeons Hold Meeting.—The railway surgeons of the Dakota, and Pierre and Rapid City divisions of the Chicago and Northwestern System met in Huron, S. Dak., September 16, at the call of Dr. John L. Foxton, district surgeon of the Dakota division, to meet the new chief surgeon of the system, Dr. George W. Hopkins, Chicago, and organized an association which will hold meetings once or twice a year.

Electrotherapeutists Meet.—At the twenty-fourth annual meeting of the American Electrotherapeutic Association held in Battle Creek, September 15 to 17, the following officers were elected: president, Dr. John W. Torbett, Marlin, Tex.; vice-presidents, Drs. Abram B. Hirsh, Philadelphia; Curran Pope, Louisville, Ky.; William Martin, Atlantic City, N. J.; Alfred J. Hopkins, Pittsburgh, and John S. Yates, Paterson, N. J.; secretary, Dr. John W. Travell, New York City (reelected), and treasurer, Dr. Emil Heuel, New York City (reelected).

Tuberculosis Conference.—The second Mississippi Valley Conference on Tuberculosis will be held at the Planters Hotel, St. Louis, October 6 to 8, in cooperation with the making of the National Association for the Study and Prevention of Tuberculosis. The purpose of the conference is to bring about a closer relationship between antituberculosis agencies in the Mississippi valley; to provide for the interchange of ideas and experiences, and to strengthen and extend the work

of the National Association and to arouse the people to the need for concerted action, both public and private, against the common foe, tuberculosis, and to bring about a closer cooperation between antituberculosis societies and other health agencies.

American Association for Study and Prevention of Infant Mortality to Meet.—The fifth annual meeting of this association will be held in Boston, November 12-14. The program will include sessions arranged by the committees on nursing and social work, pediatrics, vital and social statistics, obstetrics and public school education. Among the subjects to be discussed are included prenatal care, the need for increased and improved maternity hospital service, institutional mortality and continuation schools of home-making. The sessions will meet at the Harvard Medical School and at the Copley Plaza Hotel. Special clinics and an exhibit will be held in connection with the meeting.

Bequests and Donations.—The following bequests and donations have recently been announced:

The Western Reserve University Medical School Cleveland; a bequest of nearly \$1,000,000, in memory of Albert Fairchild Holden, by the will of his father, Liberty E. Holden, Cleveland.

Massachusetts General Hospital, Boston, \$1,000 by the will of H. R. Dalton.

Vincent Hospital, Boston, \$3,000 by the will of J. B. F. Thomas, Boston.

Mt. Sinai Hospital, \$2,000, and Hebrew Orphan Asylum, New York City, \$1,000, by the will of Arthur Klein.

Brooklyn Bureau of Charities, German, Bushwick and Swedish Hospitals, each bequests varying from \$900 to \$1,800 by the will of Jacob W. Erregger.

American Theatrical Hospital, Chicago, donation of \$5,000 by Jack Wilson to provide and equip an operating amphitheater, to be known as the Ada Lane Wilson Memorial.

Public Health in Porto Rico.—The chief of the public health service in Porto Rico, Dr. W. F. Lippitt, states that the mortality last year for the island was only 18.6 per thousand, a saving of 5,832 lives annually since 1911, when the service was organized. He declares that the change in conditions in regard to public health in such a brief period has never been surpassed and has scarcely been equaled in any country. The prompt way in which bubonic plague was stamped out when it got a foothold in the island in 1912 was the envy of other countries, especially as the effect was realized by the intelligent and energetic cooperation of the people. Dr. Lippitt has also recently sent a circular letter to all the members of the public health service saying that the sanitation service is not only for the purpose of keeping the streets clean, etc., but that it should take up all kinds of work bearing in any way on the public health, and consequently he urges each member to make a special study of some matter affecting the public health in his community, and offers the facilities of the laboratories for research or any other aid that may be required. He leaves each one free to select his own subject. The report when completed will be published in the official bulletin, credited to the author.

Plague in New Orleans.—Since the last report of bubonic plague published in THE JOURNAL of September 12, no cases of human plague have been discovered, but twenty-eight cases of rodent plague have been found, Nos. 86 to 114, inclusive, up to September 17. During the fortnight ended September 12, the Department of Outgoing Quarantine has fumigated 141 vessels with sulphur and 28 with carbon monoxid; has burned 25,116 pounds of sulphur; has consumed in carbon monoxid fumigation 32,890 pounds of coke; has inspected 40,017 tons of outgoing freight and 202,986 packages of freight; issued 81 clean and 8 foul bills of health. The Department of Overland Freight Inspection has inspected 6,573 cars; has rat-proofed 3,445 cars and has condemned 20 cars. No rodents were killed in cars during the fortnight. The Department of Field Operations has trapped 15,480 rats; has fumigated 7 premises; disinfected 145 premises; inspected 10,327 premises; has placed 515,715 poisons; has served 4,978 notices; has rat-proofed 560 buildings and has inspected 248 dead. The Department of Laboratory Examinations received 14,017 rodents, of which it has examined 9,996; 25 suspicious rats were found, and in 14 of these the diagnosis of plague was confirmed; 1 suspicious case of human plague was examined. The total number of rodents found up to September 12 was 79,543, of which 68,595 were examined.

CANADA

Health Officers of Nova Scotia.—At the recent meeting of the Medical Officers of Health of Nova Scotia, Dr. William H. Hattie, Dartmouth, provincial officer of health, presided. Among those who delivered addresses were Dr. Peter H. Bryce, Ottawa, and Dr. John W. S. McCullough, Toronto. Annual meetings will be held in the future.

Ontario Medical Association.—The next meeting of the Ontario Medical Association will be held in Peterborough in May, 1915. This meeting will be held in connection with the annual meeting of the Health Officers of Ontario. Dr. Thomas W. H. Young, Peterborough, is chairman of the Committee of Arrangements.

Personal.—Dr. W. E. Deeks has abandoned his trip to England, and is at present examining recruits in Montreal. —Dr. Campbell B. Keenan, Montreal, has accepted the position of regimental surgeon to the Princess Patricia's Light Infantry. Dr. Keenan served through the South African war as surgeon to Strathcona's Horse. —Sir Thomas Roddick has returned to Montreal. At the outbreak of the war he was in Alsace, but reached London after a very trying journey. On his return to Montreal he contracted a cold which developed into pneumonia, from which he is now said to be recovering. —Dr. Robert Rudolf, Toronto, has gone to England, where he has been called to act as medical adviser to one of the base hospitals. —Hon. Dr. Beland, who has been doing good service in a medical capacity for the Belgians, has been appointed by the Dominion government to attach himself to Canada's first contingent. —Dr. George W. Ross, Toronto, has returned from Europe.

WAR NOTES

Madras Gives Hospital.—The government of Madras has offered a fully-equipped hospital ship with a capacity of 300 beds for the use of the Indian expeditionary force.

Red Cross Hospital Opened.—Two Washington physicians, Dr. Franz A. R. Jung and his wife, Dr. Sofie Nordhoff Jung, have established an American Red Cross Hospital in Munich, with a capacity of sixty beds.

Rations of War Prisoners in England.—The British War Office has stated the following as daily rations for war prisoners: bread, 1½ pounds or biscuits, 1 pound; fresh or frozen meat, 8 ounces or preserved meat, half ration; fresh vegetables, 8 ounces; butter or margarine, 1 ounce; condensed milk, one-twentieth of 1 pound tin; tea, one-twelfth ounce, or coffee, 1 ounce; sugar, 2 ounces; salt, one-half ounce.

Canadian Physicians Off for the Front.—It is probable that Lieut.-Col. Adam T. Shillington, Ottawa, will sail with the Canadian detachment, in charge of the Base Hospital, and with him will go Lieut.-Col. Robert L. Gardner and Drs. William P. Dillon, Charles A. Young, Neil McLeod, George Howlett Bell, Charles E. Preston, Theodore A. Lomer and James Seagar, all of Ottawa. —Dr. Edward J. Williams, Sherbrooke, Que., at present in command of the Sixth Cavalry Field Ambulance, has been appointed to duty in a stationary hospital in France.

Dr. Almroth E. Wright Recommends Antityphoid Vaccination.—In a letter to the London Times, Dr. Almroth E. Wright adds his influence to the movement for antityphoid vaccination for British troops. He suggests as the author of the method that it be made compulsory. Within the last three weeks he states a total of 180,000 doses of "antisepsis" vaccine have been supplied to the British army and navy and to the French military hospitals. Besides, the Department for Therapeutic Inoculation of St. Mary's Hospital, of which Dr. Wright is the head, has furnished as a contribution for the use of the British army nearly 280,000 doses of antityphoid vaccine.

Medical Congresses Postponed.—The following item is taken from *Deutsche medizinische Wochenschrift*, Aug. 13, 1914: "We have received from Professor Oppenheim the information that the Society of German Neurologists will omit the session of their society for this year. We may assume the same for all the other medical congresses, especially the Science Association (Naturforscherversammlung). Regarding the International Medical Congress which is planned for 1917, it is said that the German Executive Committee has already announced that further preparations for this meeting are discontinued. However, . . . it may be assumed with complete certainty that in 1917 the feeling of mutual embitterment will not yet have disappeared to a sufficient extent to permit a meeting of the representatives of those nations who are now threatening each other with destruction to take place and the usual speeches of greeting on the nation-binding power of science to be made in quiet."

Shortage of Medical Men in England.—The Medical Press and Circular, September 9, says that war has already absorbed a large proportion of what may be termed the floating section of the medical profession—that is to say, those of its members who are not engaged in private medical practice or in

one of the public services. Many newly qualified men are residents in hospitals, where they gain a valuable insight into professional work. Others of various ages act as assistants or do locum tenens work. Naturally many of this class have joined the army as surgeons on the comparatively liberal terms offered for service during the war—namely, 24 shillings a day, with allowances, and £60 grant at the end of the term of service. In addition not a few practitioners have thrown up their work and gone to the front. A large number of hospital surgeons have followed their example, with the result of a serious dislocation of medical practice throughout the Kingdom. Before the war there was a shortage of medical men, a deficiency that has now been seriously aggravated. Many asylums, poor law infirmities and voluntary institutions are at their wits' end to find resident medical officers to carry out their routine work.

LONDON LETTER

London, Sept. 9, 1914.

The War

As stated in my last letter, ample preparations have been made for the reception of the wounded in the various civil hospitals throughout the country and also in military hospitals, of which many are being established. At the London Hospital as many as 500 beds—250 for the army and 250 for the navy—have been offered and have been accepted. Three hundred wounded soldiers have arrived. They were taken from the railway station by a large party consisting of resident medical officers who acted as stretcher bearers and carriers. In consequence of the enormous crowds which gathered they were admitted by a back gate. Contrary to the rule of the hospital, they have been allowed to smoke in the wards, a privilege which they greatly appreciate. At Netley there is a great military hospital and military medical school. Here 800 soldiers from the front have been admitted. Some of them are sick, some suffering from sore feet and several hundreds from gunshot wounds. Hardly any of the wounds have been caused by rifle fire; most of them are due to shrapnel bullets. This is contrary to previous experience which is that wounds from rifle bullets are the commonest.

Inquiries of the government into the question of the drug supply have shown that, while in the case of many drugs, the prices of which have risen considerably, such shortage of stocks as exists is due to temporary and easily removable causes, in other cases a considerable period may have to elapse before the small supplies at present available in the country can be replaced. In the case of some drugs, as for example, the bromids, the shortage is due to the fact that the mineral deposits from which they are at present obtained are found chiefly in Germany, while in other cases, such as that of many synthetic remedies, the manufacture is largely carried on in that country. In other cases, again, the existing shortage is due only to the general interruption of sea-borne trade which accompanied the outbreak of war, and will be relieved as shipping communications are restored. The government has appointed a committee consisting of prominent physicians to consider questions arising in connection with the supply of drugs with special reference to the ways in which the medical profession can assist in effecting economies in the use of those drugs of which the supplies are small. A confidential circular has been issued by this committee to all physicians asking them as far as possible to conserve the stock by restricting the use of drugs of which the supplies are very small and not easily renewed. These drugs have been divided into two classes: those of which the stocks are very low and possibly cannot be replenished for a considerable time, and those which, though showing some shortage at present, can soon be replenished from ordinary sources or by opening alternative sources in a short time. The first group includes salicylates, bromids, potassium salts, glycerophosphates, liquid petrolatum, synthetic benzoic acid and its salts. It is suggested that salicylates should be reserved for the treatment of acute rheumatism and that for other diseases (influenza, neuralgia and conditions loosely termed rheumatic) other drugs be used. It is suggested that bromids be used only for epileptics, that sodium bicarbonate be substituted for potash salts, and sodium sulphate and phosphate for potassium tartrate and potassium sulphate; that for mouth washes and antiseptic gargles other substances than potassium chlorate be used; that syrupus ferri phosphatis and syrupus calcii lactophosphatis be substituted for glycerophosphates; that other laxatives be used instead of liquid petrolatum, and that benzoic acid be used only when

a satisfactory substitute cannot be obtained. The second class consists of citric acid and tartaric acid, synthetic products (antipyrin, acetanilid, phenacetin, etc.), ergot, formaldehyd and its derivatives, hexamethylenamin and allied compounds and gentian root. It is suggested that instead of prescribing quinin in effervescent mixtures, acids be ordered, thus avoiding the use of citric and tartaric acid. With regard to the synthetics and analgesics it is suggested that their loss would be felt less if they were not used as antipyretics; that ergot be reserved for the treatment of post-partum hemorrhage, that formaldehyd be reserved for cases in which other disinfectants are inapplicable; that boric acid be used as a urinary anti septic instead of hexamethylenamin and its allies, and that other bitters be used instead of gentian. The question of manufacturing some of the drugs hitherto obtainable solely from Germany is being seriously considered by manufacturers.

The protection of troops in the field against typhoid fever is receiving consideration. Army medical officers in charge of home depots, garrisons and camps are strongly urged to use all their influence in securing as many volunteers as possible for inoculation against typhoid fever. Sir William Osler has written to the *Times* in support of this. He thinks it would be very difficult to prevent outbreaks of dysentery and typhoid fever, of which in the South African War more died than were killed in action. He urges that antityphoid vaccination be made compulsory in the army.

Marriages

MARY VIRGINIA McCUNE, M.D., Martinsburg, W. Va., to L. KISMET ROSSA, M.D., of Melbourne, Australia, at Harper's Ferry, W. Va., September 7.

FREDERICK B. CLARKE, M.D., Milwaukee, Wis., to Miss Agnes Myrle McCormick at Buffalo Ranch near Billings, Mont., August 31.

JOHN GRANT HARTWELL, M.D., Boston, to Miss Marion R. Gile of Colorado Springs, at her summer home in MacMahan, Me., September 2.

ROBERT BUCHANAN KENNEDY, M.D., New York City, to Miss Anna May Reimer of Rockland Lake, N. Y., September 5.

DANA FRANK CUMMINGS, M.D., Cherryfield, Me., to Mrs. Blanche Cyrene Ross Ray of Rockland, Mass., September 1.

BENJAMIN ALISON COCKRELL, M.D., Pineville, Ky., to Miss Harriet Tilghman Marimon of Valparaiso, Ind., September 2.

AUGUST HENRY ROSEBURG, M.D., Denison, Ia., to Miss Alexandria Zorin of San Diego, Cal., at Omaha, September 7.

CHARLES EDWARD PALMER, M.D., David City, Neb., to Miss Narcissa Houston Light of Cozad, Neb., September 1.

EDWARD EMMET POWERS, M.D., Rome, N. Y., to Miss Mary Catherine Reding of Dunkirk, N. Y., September 9.

ABRAHAM WILLIAM NELSON, M.D., Cincinnati, to Miss Helen Sebel of Avondale, Cincinnati, September 3.

JOSEPH S. DOUGHERTY, M.D., Lena, Wis., to Miss Josie O'Callaghan of Iron Mountain, Mich., August 25.

WILLIAM ALOYSIUS DELANEY, M.D., to Miss Elizabeth C. McHenry, both of Mitchell, S. Dak., September 3.

CHARLES MERRILL ROSE, M.D., Galesburg, Ill., to Miss Marguerite Connery of Chicago, September 21.

JOHN WILLIAM BOREN, M.D., Marinette, Wis., to Miss Esther V. Johnson of Chicago, September 1.

GRIFFITH A. DEMAY, M.D., Indianola, Neb., to Miss Elsie Portz of Uniontown, Wash., September 4.

LOUIS SHALET, M.D., to Miss Elsa Helen Adeleine Müller, both of New York City, September 11.

WILSON GEORGE SMILLIE, M.D., Boston, to Miss Faye Anderson at Denver, Colo., September 2.

HARRY W. ROSENTHAL, M.D., to Miss Ruth A. Masbach, both of Baltimore, September 9.

DAVID NISAN RAPPOPORT, M.D., to Miss Bluma C. Bayuk, both of Philadelphia, August 28.

CHARLES EDWARD VIDT, M.D., Buechel, Ky., to Miss Bernice Hughes of Louisville, June 13.

FRANK P. DWYER, M.D., Renovo, Pa., to Miss Mary Howell of Altoona, Pa., July 29.

"patent medicine" testimonial—none whatever. The exploiters of Sanatogen put forward some testimony, however, that purports to have a certain authority. This is a statement to the effect that "Sanatogen acts as a strong stimulus as far as the recuperative powers of the blood are concerned."

This claim is based on biologic experiments carried out by two physicians, Drs. G. Mann and J. G. Gage, the record of whose work was published in the *Lancet*, Oct. 19, 1912. The article of Mann and Gage was gone over with some care and the experiments there described did not seem to justify the conclusions reached by the authors. As it had been published in the *Lancet*, a medical journal of standing, whose publishers apparently thought it of sufficient importance to warrant the expense of a colored plate insert, it seemed worth while to have the work of Mann and Gage reviewed and its con-

Three series of experiments were made and reported by Drs. Mann and Gage, comparing the histology of the blood in starvation and during the height of digestion. The experiments of the first series were made on six students, the starvation period being thirty-six hours, ordinary food being taken after the thirty-six hours' fast, so far as can be gathered from Dr. Mann's report. It was found that during the height of digestion the nuclei of the lymphocytes and leukocytes stain more deeply, and that there is a slight decrease in the cytoplasm and consequent diminution in the size and number of the granules of the neutrophil and the eosinophil cells, in comparison with the blood during fasting.

The experiments of the second series were made on 100 frogs that had starved for months, blood-films being taken at varying periods after feeding 1 gm. Sanatogen. The changes noted in the white blood-cells of the frogs were practically identical with those described in the case of the six students. Increased cell division is stated to occur. The nuclei of the erythrocytes stain more deeply and the cells are increased in size, and exhibit increased cell division twenty-four hours after the feeding.

The third series consisted of one experiment on Dr. Mann himself. He fasted twenty hours and then took 15 gm. of Sanatogen in a cup of water. Practically the only change noted in the blood after the feeding was a deeper staining of the nuclei of the white cells. To quote:

"The changes in the granules of the polymorphonuclear leukocytes and in the eosinophils were much less marked than in the specimens supplied by the students, and the diminution in the size of the white cells was so insignificant as to be hardly noticeable."

Assuming that the blood-changes reported are correct, is the conclusion warranted that Sanatogen is a powerful recuperative stimulant to the blood?

In the first place, it remains to be proved, for there is as yet positively no evidence that the deeper staining of the nuclei during digestion and absorption of a protein meal represents "recuperative power of the blood" or processes of "feeding" on the part of the white cells. The actual significance of these changes requires further investigation. The increased division of the blood-cells described by Dr. Mann in the frogs was not observed by him in man. This phenomenon in the frogs is, in all probability, associated with the extraordinary length of the starvation period (months) and the well-known seasonal variations in the physiology of this species.

In the second place, waiving for the moment the question of the significance of the blood-changes observed, the evidence, so far as it goes, points to the conclusion that the greater affinity of the nuclei of the white cells for the stain is brought about by the feeding of any protein food. The experiments do not demonstrate any different or more marked effect from Sanatogen than from other protein foods.

The test on the six students with ordinary food can be considered as a control on the single Sanatogen test on Dr. Mann himself. The blood-changes in the students were more marked than in Dr. Mann.

Although Mann and Gage say that six frogs were used as controls, they do not say how the controls were treated, or draw any comparison between the controls and the frogs fed with Sanatogen. So far as the report goes, therefore, the only basis for comparison is afforded by the work of one of Dr. Mann's pupils, H. G. Butterfield. This worker, as quoted by Mann, found that on feeding newts after two weeks' starvation with a worm the size of a wooden match, the nuclei of all tissues (excepting nerve cells) take a much deeper stain than in the control animals. To pronounce Sanatogen, on the basis of the facts reported, a "powerful stimulus" to blood-formation is a piece of special pleading, if not of downright disingenuousness. Considered on its own merits, the work would not have appeared to me worthy of being repeated for the purpose of checking up such obviously unwarranted conclusions. In order to comply with the request made of me, however, I have repeated Dr. Mann's experiments:

EXPERIMENTS BY PROFESSOR CARLSON

I. TESTS ON MAN (A. J. C.)

1. 36 hours' fast followed by a meal of 25 gm. Sanatogen in water.
2. 36 hours' fast followed by a meal of 25 gm. casein in water.
3. 36 hours' fast followed by a meal of 200 c.c. of milk.

II. TESTS ON RATS

1. 4 animals, 72 hours' fast followed by a meal of Sanatogen in water.
2. 2 animals, 72 hours' fast followed by a meal of crackers and milk.

Above is a photographic reproduction of one of the exhibits made at Atlantic City at the last annual meeting of the American Medical Association.

Jar 1 contains 3½ ounces of the casein-glycerophosphate combination made abroad and sold under the name "Sanatogen;" it costs One Dollar.

Jar 2 contains 2 pounds 13½ ounces of a casein-glycerophosphate combination made by an American casein company; it costs One Dollar. For the same money, then, one gets nearly 15 times as much of this casein-glycerophosphate combination made in America as when the casein-glycerophosphate combination is sold under the name "Sanatogen" and manufactured abroad.

Jar 3 contains one dollar's worth of pure casein. The casein entirely fills the jar, although the weight of the material is the same as the weight of the casein-glycerophosphate combination in Jar 2. Pure casein is more bulky than the casein-glycerophosphate combination.

Again we would emphasize that the chief objection to Sanatogen is not its high price but the fraudulent claims under which it is sold.

clusions checked by parallel experiments. A. J. Carlson, professor of physiology at the University of Chicago, was asked to do this work and kindly undertook it. His report follows:

Report of Professor Carlson

I am asked to review the work done by Drs. G. Mann and J. G. Gage, from which they draw the following conclusions:

"Sanatogen [sodium caseinogenate glycerophosphates] further stimulates blood-cells to undergo nuclear division, which during the early period is mostly amitotic. . . . Therefore, it is evident that Sanatogen acts as a strong stimulus as far as the recuperative powers of the blood are concerned."

3. 2 animals, 72 hours' fast followed by a meal of casein in water.
4. 2 animals, 72 hours' fast followed by a meal of casein and sodium glycerophosphate in water.

Blood-films were taken at intervals during the fasting period and for twenty-four hours after feeding was resumed. The technic of fixing and staining given by Drs. Mann and Gage was followed in every detail in order to make my results comparable with their findings.

RESULTS

My results may be summarized as follows:

1. The only change in the blood-cells that could be detected with certainty in rats or in man, after feeding with Sanatogen or after feeding with other foods, was a deeper staining of the nuclei of the white cells in the films taken after feeding as compared with the films taken during fasting. This difference is generally distinct and unmistakable, although individual cells can always be found in the fasting and the feeding preparations that show no difference in affinity for the dyes. To this extent my results confirm those of Mann and Gage. I was not able, however, to make out any constant difference in the size of the cells, quantity of cytoplasm, or size and number of cytoplasmic granules similar to those reported by Mann and Gage.

2. There was no difference in the affinity for stains on the part of the white blood-cells in films taken after feeding Sanatogen and those taken after feeding milk, crackers, casein, and casein and sodium glycerophosphate. This is true for the tests both on man and on rats.

3. The above-mentioned difference in the staining of the cell nuclei was somewhat more marked in the tests on rats than in the tests on man, probably owing to the longer starvation period in the case of rats.

It has already been stated that the significance of this increased affinity for dyes in the nuclei of the white blood-cells must be determined by further investigation. It may be related to the change in the titration alkalinity of the blood rather than an evidence of "recuperative power" on the part of the blood, as it is well known that starvation induces acidosis, while during digestion the alkalinity of the blood is distinctly increased. If we assume that increased staining reaction during digestion indicates "increased recuperative power of the blood" it follows that such common and inexpensive foods as milk, crackers and casein are just as "powerful stimuli" to this recuperation as Sanatogen.

The extensive researches of Mendel and Osborne have shown that casein is in a certain sense a perfect food in that it is, in normal animals, capable of promoting growth and maintaining nitrogenous equilibrium, at least for long periods of time. The burden of proof, however, rests with the promoters of Sanatogen to show that the casein in Sanatogen is superior to the natural product of the cow.

Conclusion

From the findings in Professor Carlson's report on this disguised puff of a mendaciously exploited proprietary, about all that remains to be said is that it is humiliating to find such pseudo-science not only built up by members of a profession trained in science, but also given currency and authority by a medical journal of high standing.

The Character of Lister.—In the midst of his great triumph Lister preserved, unstained from the breath of vanity, the noble qualities of character that were his. He was ever gentle, courteous and firm. Trying as are the exactions and responsibilities of an important surgical post, Lister was never known to speak a sharp word to house surgeon, dresser or any one in his service. His scientific spirit and discovery attracted the curiosity of the students and young graduates of Edinburgh; his personal nobility won their hearts. His art of winning their loyalty was by inspiring enthusiasm and giving encouragement. "Often in the middle of a trying operation," wrote one of his pupils, "a gentle smile bestowed on us young students when we were honestly trying to do our best as assistants was most encouraging." Many of his students afterward confessed that their contact with Lister was the best and purest influence of their lives.—G. T. Wrench, *Lord Lister, His Life and Work*.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted on request.

FORMULAE FOR LIQUID SOAP

To the Editor.—I would be pleased to have you criticize the following formula for making liquid soap.

	gm. or c.c.
Sodium hydroxid	80
Potassium hydroxid	80
Cottonseed oil	1,000
Alcohol	500
Water	2,500

Dissolve the hydroxids in 500 c.c. of water. After solution has been effected, add the alcohol, and, finally, the cottonseed oil in several portions, and shake thoroughly until saponified. Finally add water sufficient to make _____.

To the soap liquid thus prepared add:

	gm. or c.c.
Potassium carbonate	30
Terpineol	12
"Evergreen A," sufficient to produce a grass-green color.	

We have been trying to make this soap for use in the operating room, but have never succeeded in making a clear solution with the formula as it stands; there has always been an insoluble residue left. I would be specially pleased to know if the quantity is to be "q. s." 2,500 c.c. or if enough water should be added after the addition of 2,500 c.c. to make complete solution.

A. E. CONTER, M.D., Chattahoochee, Fla.

ANSWER.—The trouble encountered is probably due to the fact that saponification was not complete before the addition of the remaining portion of water. The procedure should be modified to take advantage of the heat generated by the solution of the caustic alkalies in the mixture of water and alcohol, deferring the addition of the final portion of water until after all the oil has been thoroughly saponified. Add the sodium hydroxid and potassium hydroxid to 500 c.c. of water in a suitable container, add one-half the quantity, or 250 c.c., of the alcohol; then add the oil gradually with constant stirring or occasional shaking, and after a uniform emulsion has been formed allow to stand until the mixture is practically transparent, indicating that the oil has been thoroughly saponified; then add the remaining portion of alcohol and 2,500 c.c. of water. This should readily make 5,000 c.c. or more of the liquid soap which, while slightly alkaline, is not objectionably so.

A simpler formula has been suggested by Mr. Thum of the German Hospital of Philadelphia. This formula is somewhat more economical and produces a soap that is less alkaline in reaction. It may be flavored and colored to suit:

	gm. or c.c.
Sodium hydroxid	55
Potassium hydroxid	65
Cottonseed oil	800
Alcohol	500
Water	to make 5,000

Dissolve the hydroxids in 60 c.c. of water, add all of the oil and 100 c.c. of alcohol at once and stir continuously until a permanent emulsion has been formed; allow to stand until saponification is complete and add remainder of alcohol, and water sufficient to make up the volume.

USE OF TALCUM POWDERS

To the Editor:—1. Can you inform us whether talcum powder possesses any therapeutic value in the treatment of skin affections?

2. What is the effect of plain talc on the skin? Why is it good for the skin, if it is good?

3. Exactly what is the effect of boracic acid on the skin?

4. About what proportion of boracic acid to talc should a talcum powder contain to be most beneficial?

5. What is the effect on the skin of any other ingredients contained in talcum powder?

6. Do you know of any investigations made, or have you had any experience, as to the comparative value of different commercial talcum powders, and what did such investigations and experience disclose?

J. WALTER THOMPSON COMPANY, New York.

ANSWER.—1 and 2. The effect of any powder on the skin can only be somewhat protective and dehydrating. On the other hand there is a tendency to the formation of crusts and pastes, due to mixture of the powder with sweat or other secretions.

3. The effect of boracic acid is slightly antiseptic, but there is some doubt as to even this slight value when the chemical is applied in powder form.

4. The salicylated talcum powder of the National Formulary contains 10 per cent. boric acid. The importance of this powder depends rather on the salicylate, however, than on the other ingredients. Various commercial talcum powders contain small quantities of different antiseptic and perfuming agents. For absorbent purposes by far the most effective powder is magnesium carbonate powder.

5. In general it may be stated that talcum powders seem to have but little value from a therapeutic point of view, and their value esthetically must be considered entirely from the point of view of the individual employing them.

REFERENCES TO PSYCHANALYSIS

To the Editor:—Please explain or refer me to an explanation of psychanalysis.
J. A. BALSLEY, M.D., Santa Monica, Cal.

MILK OF MAGNESIA—LACTOSE OR GLUCOSE IN URINE

To the Editor:—1. Please give a formula for making milk of magnesia.

2. I have a patient who is six months pregnant; her urine gives a very decided yellow precipitate with Fehling's solution. Is there any way to determine if this is lactose or glucose except with a polariscope? We have no polariscope. B. S. A.

ANSWER.—Milk of magnesia is a synonym for magma magnesiac, an aqueous suspension of magnesium hydroxid, made by reaction between magnesium sulphate and sodium hydroxid (see National Formulary). Each teaspoonful contains about 3 grains of magnesium hydroxid. It is used as an antacid and mild laxative in adult doses of 8 c.c. (or 2 fluidrams). Unless made with water free from iron and organic matter, the magma is likely to be discolored.

2. If a specimen of urine reacts with Fehling's solution and with Nylander's test, but fails to give a reaction with phenylhydrazin and does not ferment with yeast, the presence of lactose may be inferred. If the urine be boiled with 2 per cent. sulphuric acid and then neutralized, its optical activity will be increased and it will be capable of undergoing fermentation.

DEFINITION OF A CORONER'S CASE

To the Editor:—When is a case a coroner's case in New York State? X. Y. Z., New York.

ANSWER.—Chapter 410, Section 1773, Laws of 1882, reads as follows: "If a person dies from criminal violence or by a casualty, or suddenly while in apparent health, or when unattended by a physician or in prison, or in any suspicious or unusual manner, the case must be referred to the coroner."

The following questions were asked:

PHYSIOLOGY, PATHOLOGY AND BACTERIOLOGY

1. Describe the lesions in typhoid fever. Outline the laboratory tests for verifying the diagnosis. 2. Describe the lesions, name the causes and outline the laboratory technic for demonstrating the varieties of inflammations of the eyes of the newborn. 3. Give a case of incipient tuberculosis of the lungs. Outline the laboratory tests that would aid in confirming the diagnosis. 4. Give an acute case of peritonitis (a) how are the toxins absorbed? (b) discuss the rationale of the sitting position and enteroclysis in the treatment of the above condition. 5. Given a case of gonorrheal infection, describe the heart lesions that may result. Contrast the disturbed functions of such a heart with the functions of a normal heart. 6. Contrast the blood-picture in leukemia and pernicious anemia with that of normal blood. 7. Describe the lesion in (a) gastric ulcer; (b) carcinoma of the stomach. Differentiate these lesions by laboratory methods. 8. Differentiate, by an examination of the spinal fluid, the various forms of meningitis. 9. Name two pathologic

conditions that usually have icterus as a symptom. What is the significance of icterus, (a) as regards the liver? (b) as regards digestion? 10. Briefly describe the types of gangrene. What is understood by the "line of demarcation?"

DIAGNOSIS, SYMPTOMATOLOGY, TOXICOLOGY AND MEDICAL JURISPRUDENCE

1. Describe the symptoms of the various forms of asthma, and differentiate them from chronic bronchitis. 2. State in detail the symptoms diagnostic of ileus, and name four conditions which may cause it. 3. Describe the symptoms of diphtheria and differentiate it from follicular tonsillitis. 4. State the symptoms of rubella (Roetheln) and differentiate it from measles, scarlet fever and urticaria. 5. Describe the symptoms diagnostic of gonorrheal arthritis, and differentiate it from tubercular joint. 6. State the symptoms of iritis and differentiate it from glaucoma and keratitis. 7. Differentiate aortic regurgitation from mitral regurgitation. 8. Enumerate the symptoms of a poisonous dose of (a) bichlorid of mercury; (b) aconite; (c) arsenic. Give the immediate treatment for each one. 9. On what data would you base a diagnosis of (a) syphilis? (b) tetanus? (c) gonorrhea? Name one laboratory test for each. 10. What precautions, from a medicolegal standpoint, should the physician or surgeon exercise when treating fractures or dislocations?

OBSTETRICS, GYNECOLOGY AND PHYSIOLOGICAL CHEMISTRY

1. Enumerate the causes of backward displacement of the womb, (a) in nulliparas, (b) in multiparas. Discuss the treatment in each case with reasons for the same. (Omit description of operation). 2. Give the methods of making an early diagnosis of cancer of the uterus, (a) cervix, (b) fundus. Outline an appropriate treatment for each. (Omit description of operation.) 5. Outline a satisfactory preparatory treatment for plastic operations on the vagina, giving reasons for each step. 4. Name four abdominal enlargements which may be mistaken for advanced pregnancy (seven months or more) and differentiate each from such possible pregnancy. 5. State the probable causes of vomiting of pregnancy. What methods would you adopt for its relief and state the theory on which you would use the remedies advised. 6. Given a pregnant woman (the first three months), what symptoms would indicate a possible abortion? In case the abortion occurred, how would you treat the case? (Omit description of operation.) 7. Discuss the various toxemias of pregnancy from the viewpoint of premonitory symptoms. Discuss their treatment (a) prophylactic, (b) after having become well established. 8. Give arguments for and against the so-called low protein food standard. 9. Explain the relationship between the pigment of the blood, bile and feces. 10. Explain the processes of physiological chemistry by which indican is ultimately eliminated and where is it ultimately found.

SURGERY AND ANATOMY

1. State the avenues and possible points of metastasis of a malignant growth of the breast. On what symptoms may an early diagnosis of cancer of the breast be based? 2. State (a) what structures may be injured in a subcoracoid luxation of the humerus. (b) How may this condition be recognized? (c) How may it be corrected? 3. Name three usual causes of rectal strictures. Outline (without details) a palliative operation for this condition. 4. Enumerate (without explanations or details) conditions which might exist in a patient tending to complicate and render more dangerous a surgical operation. 5. What conditions would call for catheterization of the male bladder? Describe in detail a proper method. 6. Describe (a) a method of preventing surgical shock; (b) its treatment. 7. In the case of an abdominal operation, give in detail (a) a method of preparing the patient; (b) the surgeon. Give reasons for each step. 8. Outline (a) methods of prevention; (b) the treatment of bed sores. 9. In fractures of the upper third of the femur, what is the usual position of the fragments? What muscular action causes the same? 10. What anatomic structures are involved in flat-foot? What methods of treatment would you adopt for its correction?

PRACTICE AND THERAPEUTICS AND MATERIA MEDICA, HYGIENE AND PREVENTIVE MEDICINE

1. Describe the therapeutic action of suprarenal gland, thyroid gland and pituitary body. 2. Outline the management of a case of syphilis in both the primary and tertiary stages. 3. Name two remedies and the indications for their use in each of the following conditions: 1, impetigo contagiosa; 2, scabies; 3, tapeworm; 4, hemoptysis; 5, croup (non-diphtheritic). 4. Name and describe three methods for the purification of water intended for drinking purposes. 5. On what theories or principles are cold baths and cold sponging resorted to? State the indications calling for such measures. 6. Give in detail the dietetic and hygienic rules and regulations you would prescribe in a case of diabetes mellitus. 7. Outline the management of a case of nocturnal enuresis. 8. Explain the difference between the principles underlying vaccine therapy and serum therapy. State the character of danger in their application to the human body. 9. What errors in diet or hygiene or occupational conditions may cause or aggravate acute eczema? Write a prescription for a suitable application stating the special purposes expected to be accomplished. State one drug to be used internally, with the reasons for its employment. 10. Give the hygienic measures tending to prevent epidemic "colds." Give the management of an acute attack, including three remedies and reasons for their use.

Book Notices

RADIUM AND RADIO-THERAPY. Radium, Thorium and Other Radio-Active Elements in Medicine and Surgery. By William S. Newcomet, M.D., Professor of Roentgenology, Temple University. Cloth. Price, \$2.25 net. Pp. 315, with 72 illustrations. Philadelphia: Lea & Febiger, 1914.

The knowledge of radium introduces the physician to a strange world. When one begins to talk of transformations of one element into another, the chemical ideas in which many physicians now in practice were educated are out-raged; and when the exact length of life of elements varying from two minutes to 8,000,000,000 years is calculated, one can only wonder what science will next bring forth. It must be acknowledged that radium is a powerful agent and at the same time a dangerous one, and if the physician is to handle this new power he must have a thorough knowledge of its capabilities and limitations. This means that he must have a new education in a large field of chemistry. Owing to the cost of the material this knowledge can be gained by approved methods of experimental science only to a limited extent. Text-books must be resorted to, and for this purpose the present work is very well adapted. The practical consideration of the therapeutic use of the radio-active elements is conservative, but up to date. The author gives the following estimate of the value of these preparations in internal medicine:

"The exact status of these radio-active elements in internal medicine is by no means a settled question; perhaps the observations in some instances have been greatly exaggerated; yet, at the same time, from an experimental standpoint these elements produce changes which have been noted by most careful observers, who practically agree on the salient points, and from their deductions it is rational to adopt some of the conclusions which have brought about the application of these elements. But as most of the diseases in which they have been employed belong to a class for which certain forms of treatment have been periodically promulgated, to be used for a short time and finally be forgotten, more proof must be given of their efficiency before they can be universally adopted."

This book will be found serviceable to medical men, both to those who are using or who propose to use radium as well as to those who want to familiarize themselves with all knowledge regarding it.

THERAPEUTICS, DIETETICS AND HYGIENE. An Australian Text-Book. By John William Springthorpe, M.A., M.D., M.R.C.P., Senior Physician to the Melbourne Hospital. Two Volumes. Cloth. Price, 25 shillings net per volume. Pp. 1120, with illustrations. Melbourne: James Little, 1914.

Australia is a new continent with new ideals which extend to the domain of medicine and hygiene as well as to politics and sociology. Among the physical ideals is the hope that by the culture of a pure white race a state of physical perfection may be attained which will outstrip anything that the world has yet seen. Dr. Springthorpe has entitled his work an Australian text-book, intimating at least that it expresses something of the high aims of Australian medicine. It is published in two volumes. One characteristic of the author's work is the attempt to correlate the psychic and the physical and to base his science as well as his practical methods on a philosophy which recognizes mind associated with matter, if not supreme over it, in the whole realm of science. Hence he includes mental and moral influences in his study of the causes of disease and in the consideration of the methods of hygiene. Aside from the peculiar point of view given by the fact that this is especially an Australian text-book, attention must be called to the prominence given throughout the book to the public relations of hygiene. The subject of education is discussed from the intellectual and emotional side as well as the physical. The portrayal of child life is not limited to a description of physical degenerations and deformities, but takes in the effect of immoral environment as well. The author indulges in much philosophizing and quotes some interesting passages which appear

What is Scholarship?—The answer is: The discovering, the organizing and the explaining of new facts. Only the uninformed and unscholarly are in the habit of designating the mere diffusion of knowledge as scholarship.—F. C. Brown, —Science.

to have little to do with the immediate subject. On the topic of public hygiene the author gives some valuable observations on the topographic peculiarities of the different parts of Australia, giving its climate conditions with some detail. The subjects of water-supply, sewage, ventilation, housing, clothing and hygienic habits are discussed with special relation to the national needs and peculiarities.

The volume on therapeutics is less local and presents the remedies and principles of treatment which are familiar to other parts of the civilized world. There is a description of Australian mineral springs, watering places and sanatoriums. No note seems to be made of an indigenous vegetable materia medica. Vaccine therapy receives due consideration. In approaching radiotherapy the author again indulges in some speculation and recalls the fact that "to-day science confidently bases the whole of physics and chemistry on an ethereal substratum." Further on he says: "Hence in the most modern refinements of therapeutics we find ourselves in the ethereal stage, and separated by the narrowest of margins, if separated at all, from the immaterial and the psychical. Thus in x-rays, radiotherapy and ionic medication, we are close to the very essence of things, and to the very origin of life itself." The chapter on this subject is, however, not very long, and the powers attributed to radium are very moderate. The volume is concluded by a chapter entitled "Therapeutic Memorabilia" which contains a large number of hints on the treatment of a variety of diseases.

To one who can find in the expressions of therapeutists a finger pointing to future developments of the healing art, these two volumes with their antipodal flavor and their philosophic trend may indicate a new phase of medical teaching. Their scientific value is somewhat diminished by the rhetorical padding, which, although good in itself, is not exactly scientific. They form interesting reading, but it is unfortunate that their typography in many places does no credit to Australian printing. They are illustrated by a number of very good plates.

THEORIE UND PRAXIS DER BLUTENTZIEHUNG, NACH DEM GEGENWÄRTIGEN STANDE DER WISSENSCHAFT BEARBEITET. Von Prof. Dr. Heinrich Stern, Oberarzt für Innere Medizin am St. Mark's Hospital, New York. Paper. Price, 3.50 marks. Pp. 144, with 15 illustrations. Würzburg: Curt Kabitzsch, 1914.

It is at any rate an interesting if not important indication of the international character of our medical literature that an increasing number of American physicians contribute to German journals and publish more or less extensive works in the German language. The present work by Dr. Stern is an example of this tendency. The subject is as old as medicine, and while the present century presents the lowest ebb of bloodletting in therapeutics, yet enough scientific fact and clinical experience are found to constitute a very good defense of the ancient practice. While it is safe to say that a very large portion of the present generation of physicians have no experience in the use of the lancet, it may very well be that an extension of this method would follow if those who know little or nothing of it would give time to a careful perusal of the evidence in favor of this powerful mode of influencing the blood-pressure and the metabolism. There appears to be a lack of monographs on this subject in English which we may hope to see supplied either by a translation of Stern's work or by the publication of a new one.

TEXT-BOOK OF ANATOMY AND PHYSIOLOGY FOR TRAINING SCHOOLS AND OTHER EDUCATIONAL INSTITUTIONS. By Elizabeth R. Bundy, M.D., Member of the Medical Staff of the Woman's Hospital of Philadelphia. Third Edition. Cloth. Price, \$1.75 net. Pp. 408, with 233 illustrations. Philadelphia: P. Blakiston's Son & Co., 1914.

This work ought to be entitled "Applied Anatomy and Physiology," as nearly every chapter ends with a paragraph or two headed "Surgical Notes" or "Clinical Notes," and this of course adds greatly to the value of the book. The illustrations are well selected. There is a table of systemic arteries in the old nomenclature, and tables of the systemic arteries and veins according to the Basle anatomic nomenclature. There is an excellent glossary which, however, does not give the origin of the words.

Medicolegal

Entitled to Recover for Quarantining Infantile Paralysis (Shidler vs. York County (Neb.), 146 N. W. R. 949)

The Supreme Court of Nebraska holds that a duly licensed physician, acting under the order of the State Board of Health in quarantining and suppressing a highly contagious disease, may recover of the county, where such disease was prevalent, the actual expenses incurred by him and the reasonable value of his services. The court says that in the summer and fall of 1909 there was a large number of cases of what is commonly called "infantile paralysis" in York County. Many of the communities in the stricken territory were thrown into a condition approaching panic, and notably among those communities was the city of York in York County. The then chairman of the county board of health expressed himself as opposed to a quarantine, and failed and refused to call a meeting of the county board of health, or to take any other measures relative to the disease, or to the investigation or control of it, and, on July 20, 1909, the State Board of Health ordered that said disease be quarantined in York County, and by its order instructed the state health inspector to communicate its order to the plaintiff, and to require him to establish and maintain a rigid quarantine of said disease throughout that county. The plaintiff, a duly licensed physician, was at that time a member of the board of health in that county, but he was not the county physician, and was under no contract with, and received no salary from, the county, as a member of its board of health or otherwise. He proceeded to quarantine the disease wherever he could find it in his county, and was occupied with his duties in that behalf from about July 20 to October 1. It appeared that he came into contact personally with about 250 cases of the disease, and devoted his time to those cases to the partial exclusion of his other practice; that, in the performance of those duties, he incurred and paid necessary expenses in the sum of \$225; that for his own services in the premises he charged the county supervisors the sum of \$267.50. From this latter sum there was deducted four or five items for the quarantine of cases within the proper limits of certain towns and villages. The board of supervisors rejected his claim, but the District Court rendered a judgment in his favor, against the county, for \$508.60 and costs taxed at \$14.75. That judgment is now affirmed, because, as the Supreme Court views the case, the county was liable to Dr. Shidler for the reasonable value of his services, and the expenses necessarily incurred by him in rendering them.

Physician Not Liable for Hot-Water Bottle Injury in Hospital

(Stewart et al. vs. Manasses (Pa.), 90 Atl. R. 574)

The Supreme Court of Pennsylvania says that this action was against the family physician of a woman, by whose advice she went to a public hospital for a surgical operation. After the operation she was burned by a hot-water bottle that had been left by a hospital nurse in the bed in which she was placed. Recovery of damages was sought on the ground that the injury was caused by the negligence of the defendant, or that of the nurse, for whose action he was answerable. It was alleged that the defendant agreed to perform the operation, and to treat the patient with care and skill while under his charge, and to furnish her the services of a skilful nurse, and that he failed in the performance of his duty in this regard. The evidence showed that the defendant was a member of the associated staff of the hospital and had the privilege of sending patients there for treatment either by himself or by the regular hospital physicians and surgeons; that he agreed for a stipulated sum to perform the operation, but the hospital expenses were to be paid by the patient, to whom he gave a letter of introduction that secured her admission to a private room in the hospital; that she was prepared for the operation by hospital nurses

under the direction of the directress of nurses and etherized by a physician employed by the hospital for that purpose; that she was operated on by the chief hospital surgeon assisted by the defendant, and was removed from the operating-room to the recovery room by hospital nurses and the physician who had etherized her; that the defendant followed them into the recovery room and stood near the foot of the bed when she was placed in it; that the duty of preparing the beds in the recovery room and placing the patients therein rested entirely with the directress and the hospital nurses, the surgeons having nothing to do with it, and that this was the general rule in hospitals. Under these circumstances there was no liability on the part of the defendant for the injury caused by the negligence of a hospital nurse, and a non-suit was properly entered.

Medical Witnesses Need Not Be Licensed Physicians in State

(*Rugenstein vs. Ottenheimer (Ore.)*, 140 Pac. R. 747)

The Supreme Court of Oregon holds that the fact that a medical witness called in this personal injury case was not a physician regularly licensed to practice in that state did not militate against his competency as an expert. The only object of license is to prevent an unqualified person from practicing medicine and surgery; but a man may be ever so learned and well qualified to give an opinion, and yet not be engaged in practice. It is the duty and within the province of the court as a preliminary question of fact to determine whether or not the witness is qualified as an expert, to the end that he may give an opinion in evidence, and the appellate courts will not disturb the decision of the trial court, unless there is no evidence to sustain the preliminary decision of that court. The fact that the witness in question had been licensed to practice medicine in California, and had been so engaged since, was competent evidence for the consideration of the court in determining his fitness as an expert witness.

COLORADO STATE MEDICAL SOCIETY

Forty-Fourth Annual Meeting, held at Boulder, Sept. 9-11, 1914

The President, Dr. O. M. GILBERT, Boulder, in the Chair

Rôle of Chronic Intestinal Indigestion in Children in Production of Epilepsy

DR. J. W. AMESSE, Denver: Intestinal putrefaction, associated with chronic constipation and chronic intestinal indigestion, forms one of the most important etiologic factors in arousing epileptic paroxysms. In general, disorders of digestion have been shown to be more concerned with the nervous instability of children than is commonly supposed. The management of these cases involves the most rigid survey of domestic and personal hygiene. Whether the toxemia is or is not associated with major disturbances of the nervous system, isolation of the child, preferably in a hospital, is most desirable. Where, as will obtain in the great majority of cases, this separation from the home is not feasible, the absolute cooperation of mother and nurse is indispensable. The

hygienic management will not only embrace a proper dietary, but full instructions in writing must be furnished regarding hours of sleep, the character and amount of exercise, periods of rest, baths, fresh air and suitable clothing. In my experience these children are usually heavy milk drinkers, the balance of their ration consisting of starch in the form of potato, bread, rice, etc. The distention of the abdomen from the flatulence invariably set up by this diet is apparent on first examination. The most effective method is to change the food from a carbohydrate to protein ration, depending on albumin-milk, fermented milk, or buttermilk for a beverage only.

DISCUSSION

DR. HERBERT B. WHITNEY, Denver: The healthy stomach has a great deal of reserve power and will digest almost anything. There are cases, however, of disease of the stomach largely inherited, a nervous condition which predisposes to epilepsy. Where there is chronic indigestion at about the age of 6, 8 or 10 years, we have a difficult problem so far as treatment is concerned, and these cases demand a more accurate knowledge of dietetic principles in the treatment of dyspepsia in infancy itself. I am accustomed to put these children on an exclusively milk diet and gradually go on to the so-called antifermentive diet which comprises chiefly meats, eggs, vegetables, spinach, with exclusion of all sugars and starches, and also some forms of toast and bread, with soups, especially bouillon and consomme, etc.

DR. J. A. BLACK, Pueblo: I have in mind two children who were nearly of the same age. They were born of parents of the same character and moved in the same class of society. One child was a boy, the other a girl. One child was breast-fed and developed into a beautiful baby. The other child when born was a puny struggling little thing. The mother of the child that was bottle-fed followed instructions. After two or three months the child began to grow rapidly. The child is now 5 years of age and has never had a day's sickness. The other child that was breast-fed was allowed to eat indiscriminately all kinds of candies and cakes and the result was in a few months it developed gastro-intestinal trouble. After a few months or years the child had an attack of rheumatism and at the present time it is bordering on chorea.

DR. FRANK P. GENGENBACH, Denver: A girl at the age of puberty had some convulsive attacks. She was very frail, thin, had grown rapidly, was of marked nervous temperament and was a big eater. She would fall over and have a certain amount of twitching, but her face would be pallid rather than congested. She had several of these attacks a few weeks apart. Dr. Pershing decided that the child had beginning epilepsy, and recommended that she be put on bromids. As her blood-pressure was rather low she was given digitalis, and as she was anemic she was given iron, nux vomica, general stomachics, and he suggested a curtailment of the diet, and that the processes of elimination be looked after. As a result of this line of treatment the child did not have another attack for over a year, and then an attack was brought on by overeating. It was the last attack the girl had.

DR. H. G. WETHERILL, Denver: From 1882 to 1884 I was intern in the New Jersey State Asylum in Trenton, and in investigating the peripheral irritations which gave rise to epilepsy I found we had in that institution thirty-three male epileptics of varying ages, many of them boys. I made a careful study of the relationship of the epilepsy in these thirty-three males to phimosis. I found many of them needed circumcision. We started a campaign of this operation for the younger ones particularly, and the effect on the epilepsy for the first few months was marked. There can be no possible question that peripheral irritations, such as accompany phimosis and intestinal troubles from indigestion and improper feeding, have a very definite causative effect in producing these conditions.

Nasal Treatment of Dysmenorrhea

DR. L. B. LOCKARD, Denver: It has long been established that a definite physiologic and pathologic relationship exists

between the nose and throat and the sexual organs, particularly in the female, but the clinical significance of this relationship has not been grasped by the profession at large.

We have no way of foretelling in an individual case whether it is one of nasal dysmenorrhea or whether the pain is due to pelvic lesions. Complete failures have resulted in cases in which no pelvic disease has been demonstrable, and, on the other hand, some of the most brilliant results have occurred in individuals in whom various uterine and ovarian abnormalities existed. As a general rule it may be said that patients without organic disease of the sexual organs offer the most promising prognosis.

DISCUSSION

DR. T. E. CARMODY, Denver: Many nervous conditions affect the nose as well as the sexual organs. Headaches due to menstrual disorders are frequently relieved by packing the nose with cocain.

DR. H. A. SMITH, Delta: A girl came to me five years ago with obstruction on one side of the nose. I removed a spur of bone about half an inch in diameter from the anterior end of the middle turbinate. Nothing was said about any gynecologic condition. A year later her mother told me that she had not had any pain since her nose was operated on, whereas prior to that time she suffered a good deal of pain. The psychic effect must be left out of that case.

DR. ROBERT LEVY, Denver: In spite of a great many attempts to prove scientifically that there is a distinct relation between the nose and the genital organs, I think we must in the ultimate analysis conclude that many of these remarkable effects, if not all of them, are psychic.

Typical and Atypical Cases of Addison's Disease

DR. GEORGE H. CATTERMOLLE, Boulder: My first case was that of a minister, 29 years old, who came to Colorado on account of pulmonary tuberculosis. He received tuberculin treatment for about six months and was much improved, so that he engaged in outdoor occupations. Finally, in the spring of 1909, he took up the work of a house-painter, which kept him outside and constantly exposed to the sun, so that the first bronzing was thought to be tan. A little later, however, the bronzing became more intense and was noticed over the portions of the body protected by the clothing. This was a typical case of Addison's disease, showing the bronzing, asthenia and digestive symptoms. With the bronzing there was a loss of strength and then failure of appetite and diarrhea. At necropsy the left lung showed a healed cavity at the apex. There was no active trouble apparent in the lungs. The suprarenals showed enlargement and were both calcareous and caseous.

The second case was that of a married woman, 27 years old, who was sent to Boulder in August, 1913, because she was not getting along well at home. She had been coughing for four or five years and had a bad tuberculous family history. Examination of the chest showed only limited involvement in the apices. There was pain in the right lumbar region which had existed for several months. The peculiarity in this case was the slight amount of discoloration in the skin. There was an anemic pallor with an uncertain fawn color, but not a typical bronzing. At her home she had been kept in the sunshine and this could account for some tanning. We could not account for so much prostration, for such feeble circulation, and so much digestive disturbance resulting from the pulmonary trouble. In those cases of tuberculosis in which the prostration is greater than can be accounted for by the trouble in the lung, we should remember the possibility of the chromaffin system being diseased and possibly try the use of the suprarenal gland or its products as a therapeutic test and a remedial agent.

(To be continued)

The Last Word in Diagnosis.—There is no sign or symptom that may not be fallacious. The most experienced judgment is fallible.—Arthur E. Giles, *Clinical Journal*.

1. **Congenital Heart Disease.**—The following rules for differential diagnosis are given by Dunn. A case showing cyanosis with enlargement of the cardiac dulness or palpable thrill, or both, is one of pulmonary stenosis. If the baby dies shortly after birth, the most probable lesion is pulmonary stenosis alone. If the baby survives early infancy, or lives on into childhood, the pulmonary stenosis is probably associated with some other lesions. If the murmur is notably transmitted into the vessels of the neck, or if a "humming top" murmur is present, the additional lesion is probably open ductus arteriosus. If the murmur has neither of these characteristics, the complicating lesion is probably defective interventricular septum.

A case showing a murmur and enlargement, without cyanosis, is probably defective interventricular septum. If the murmur is not transmitted into the vessels of the neck, this lesion exists alone. If the murmur is so transmitted, or if the "humming-top" murmur is present, the lesion is probably combined with open ductus arteriosus. A case showing a murmur, without either cyanosis or enlargement, especially if the murmur is markedly transmitted into the vessels of the neck, or if it extends into diastole, is probably one of open ductus arteriosus alone. If the murmur is of the "humming-top" variety, extending throughout the cardiac cycle, the diagnosis of this lesion is almost certain.

The prognosis of the various congenital cardiac lesions and their combinations, Dunn says, does not vary with the character of the lesions except in two forms, namely, pulmonary stenosis alone, and open ductus arteriosus alone. In all the other forms and combinations there is evidence that any patient may survive, and even live to adult life. On the other hand, the evidence shows that development and nutrition suffer to a varying degree, and that the children are in general less resistant, many of them dying young of various additional affections, such as the gastro-intestinal or infectious diseases. The prognosis in babies cyanotic at birth is grave, as many of them have pulmonary stenosis alone, and die within a very short time. In those who survive, the pulmonary stenosis is probably combined with some compensating lesion, and is that of congenital cardiac disease in general. In cases which show the clinical picture of open ductus arteriosus alone, the prognosis is very good. The patients do not usually show any interference with development or nutrition, but develop normally, with eventual disappearance of the signs of cardiac disease.

2. **Whey Modified Milk.**—Of 54 infants who received whey modified milk very good results were obtained in 36 cases, fairly good results in 10 cases and poor results in 8 cases. Two cases in infants over 6 months of age, 2 cases of atrophy, 1 case of exudative diathesis, 1 case of influenza, 1 case of enteritis and 1 case of nervous vomiting did not do well on whey modified milk. Based on the results obtained by Leopold while using 'Schloss' whey modified milk during a period of two years he offers the following conclusions: Whey modified milk is indicated whenever breast milk is not obtainable. Much better results are obtained with this milk mixture than with any other method of artificial feeding, in institutions where milk is especially

indicated in very young infants, and in infants under 3 months of age.

3. **Bovine Tuberculosis.**—McCleave maintains that it is unquestionably the duty of physicians to instruct their patients and the public that bovine tuberculosis is, without giving it undue weight and always keeping it in proper subordination to the larger problem of infection from human sources, a grave menace to human health, but that it is, by the simple expedient of home pasteurization, a disease most easily prevented in man.

4. **Influence of Lactose on Metabolism of an Infant.**—Talbot and Hill claim that increasing amounts of sugar up to a certain limit increase the retention of nitrogen, and beyond that point may diminish the absorption and possibly the retention of nitrogen. Increasing amounts of sugar do not affect the absorption of fat up to a certain point, beyond which point there may be a diminished absorption of fat. Sugar given beyond certain limits may result in a greatly increased acidity of the stool and diarrhea. The diarrhea is probably a result of the increased peristalsis. Clinical evidence of a carbohydrate fermentation is the scalded, irritated skin of the buttocks and the green, watery acid stools. The retention of ash seems to depend on the amount of sugar in the food. When the amount of sugar is increased beyond a certain point, there may be a negative balance and the ash may be lost from the body. It is impossible to say whether this negative balance is due to the diarrhea, or the increased acidity of the stool, or other factors in which fat plays a part. Clinically, the amount of sugar which an infant can digest and absorb varies with the individual. There is no fixed point in a given individual at which sugar will or will not be digested at a given time. Other factors than the amount of sugar may influence its digestion.

6. **Fat in Tuberculosis.**—The series of cases reported by Schlutz comprises all the common forms of tuberculosis and includes four cases with pulmonary involvement alone, four with pulmonary glandular involvement, three with pronounced glandular involvement only, three cases of bone tuberculosis, in one of which there was also marked glandular involvement and one in which there was pulmonary and suspected peritoneal involvement. The fat absorption is distinctly diminished only in the glandular type of tuberculosis. The stools in three of the cases showed both macroscopic and microscopic evidence of fat, considerably in excess of the normal. The same was shown by the quantitative determinations. In all the other forms of tuberculosis the fat absorption very nearly approached the normal. The one case suspected as peritoneal showed good fat absorption. This study brought out the interesting fact that the fat absorption was if anything improved by the addition of certain amounts of carbohydrate to the diet.

The results of this series of cases seem to show in Schlutz's opinion that fat absorption in most of the common forms of tuberculosis is practically normal and is likely to be diminished only in those cases in which there is extensive glandular and lymphatic involvement. If it were a question of fat absorption only, high fat feeding would not be contra-indicated in most forms of tuberculosis. To what extent scrofulous or exudative manifestations, apparently unfavorably influenced by fat-rich food, should influence the diet of the tuberculous child, Schlutz says, is a question which the individual case must determine. The presence of the exudative condition apparently does not influence fat absorption. Experimental and clinical evidence both seem to show that a diet which insures the largest amount of fat deposit in the tissue, with the least retention of water, is the one most beneficial to the tuberculous child.

34. **Parameningococcus and Its Antiserum.**—The parameningococci of Dopter, Wollstein states, are culturally indistinguishable from true or normal meningococci, but serologically they exhibit differences as regards agglutination, opsonization and complement deviation. Because of the variations and irregularities of serum reactions existing among otherwise normal strains of meningococci it does not seem either possible or desirable to separate the parameningococci into a strictly definite class. It appears desirable to consider them as constituting a special strain among meningococci, not, however, wholly consistent in itself. The distinctions in serum reactions between normal and parameningococci are supported by the differences in protective effects of the monovalent immune sera on infection in guinea-pigs and monkeys. It is therefore concluded by Wollstein that it is highly desirable to employ strains of parameningococcus in the preparation of the usual polyvalent antimeningococci serum. It remains to be determined whether it is better to employ the parameningococci along with normal meningococci in immunizing horses, or to employ normal and para strains separately in the immunization process and to combine afterward, in certain proportions, the sera from the two kinds of immunized horses.

35. **Metabolism in Acromegaly.**—A distinct retention of calcium, magnesium and phosphorus was noted by the author.

which was not accompanied by corresponding changes in general metabolism as evidenced by a practical balance of nitrogen and sulphur. It is concluded that there is a primary disturbance in the metabolism of the mineral elements mentioned, with the probable formation of new bony tissue. The distribution of elements between urine and feces shows no abnormal variations.

36. Calcium Metabolism after Thyroparathyroidectomy.—The metabolism of calcium was studied by the authors in a man after complete removal of the thyroid and parathyroid glands. A slight retention of calcium (0.4578 of a gm. of calcium oxid in the ten-day period) was noted. The urinary calcium excretion was low, averaging 0.0134 of a gm. per day on a daily ingestion averaging 1.6736 gm. of calcium oxid. A slight increase was observed during the period of study in the calcium content of the blood. No symptoms of tetany were noted in the patient, who survived operation thirty-nine days. The low urinary and blood-calcium values are taken to show deficient absorption of calcium, which may bear some relation to the decreased gastric secretion after parathyroidectomy. Attempts are made to explain the non-occurrence of tetany as due to the high calcium intake and to the development of a compensatory mechanism in which the pituitary body may play a part.

37. Bacteria in Circulating Blood.—When rabbits are injected intravenously with a quantity of virulent streptococci or pneumococci sufficient to cause death within two to four days the septicemia takes a definite course with slight variations. The bacteria rapidly decrease in number from the time of the injection to from two to four hours, at which time the blood is sterile or contains only a few bacteria. Within five to six hours the bacteria reappear in the blood and steadily increase until the death of the animal. If the bacteria are less virulent, the same quantity of culture causes a chronic type of infection. The same initial decrease in the number of bacteria occurs. The reentrance into the blood is somewhat delayed, the septicemia does not reach the height obtained in the acute cases, and a second fall occurs within the course of a few hours. These rabbits show a low blood-invasion or a sterile blood-culture for several days. During this time they become emaciated to a marked degree. Then the low septicemia rapidly rises or the rabbit with a sterile culture develops a severe septicemia within a few hours and death takes place from a few hours to two days thereafter. In this type of infection local lesions, pericarditis, pleurisy, peritonitis, etc., are usually found. In the infections which run an acute course no gross lesions are found.

If the bacteria are still less virulent they never reenter the blood after the initial disappearance and the rabbits remain in good condition. Variations in the natural resistance of individual animals may be sufficient to cause quite marked irregularities in the course of the infection. Pneumococci can be standardized so as to produce a particular type of infection more easily than streptococci. In general infections such as those produced by streptococci and pneumococci the number of the bacteria present in the circulating blood at a given time supplies accurate and delicate information regarding the severity of the disease.

A large number of bacteria found in the blood and tissues at autopsy do not necessarily prove the existence of a heavy infection before the onset of the death agony, since it is a well-known fact that bacteria multiply with enormous rapidity, once the natural resistance of the animal has been overcome. Again, the individual animals of the same species, age and apparently of identical physical condition react to the aggressive force of the infecting organisms variously. This fact is readily found out by the injection of a series of rabbits with lethal quantities of bacteria per body-weight, and by making tests at various periods before death results, which, in the case of streptococci, ranges from one to six days.

38. Localization of Virus of Epidemic Poliomyelitis.—Flexner and Amoss hold that the virus of poliomyelitis is capable of penetrating the retina without producing apparent injury, to reach the central nervous organs. The virus

injected into the blood is deposited promptly in the spleen and bone-marrow, but not in the kidneys, spinal cord or brain. Notwithstanding the affinity which the nervous tissues possess for the virus, it is not removed from the blood by the spinal cord and brain until the chorioid plexus and blood-vessels have suffered injury. The intervertebral ganglia remove the virus from the blood earlier than do the spinal cord and brain.

An aseptic inflammation produced by an intraspinal injection of horse-serum facilitates and insures the passage of the virus to the central nervous organs, and the production of paralysis. The unaided virus, even when present in large amounts, passes inconstantly from the blood to the substance of the spinal cord and brain. When the virus within the blood fails to gain access to the central nervous organs, and to set up paralysis it is destroyed by the body, in course of which destruction it undergoes, as a result of the action of the spleen and, perhaps, other organs, diminution of virulence.

The histologic lesions that follow the intravenous injections of the virus in some, but not in all, cases differ from those which result from intraneural modes of infection. In escaping from the blood into the spinal cord and brain, the virus causes a lymphatic invasion of the chorioid plexus and widespread perivascular infiltration, and from the latter cellular invasions enter the nervous tissues. A similar lymphoid infiltration of the chorioid plexus may arise also from an intracerebral injection of the virus.

The histologic lesions present in the central nervous organs in human cases of poliomyelitis correspond to those that arise from the intraneural method of infection in the monkey. The virus in transit from the blood through the cerebrospinal fluid to the substance of the spinal cord and brain is capable of being neutralized by intraspinal injection of immune serum, whereby the production of paralysis is averted. The experiments described support the view that infection in epidemic poliomyelitis in man is local and neural, and by way of the lymphatics, and not general and by way of the blood. Hence Flexner and Amoss uphold the belief that the infection atriun is the upper respiratory mucous membrane.

39. Experimental Tuberculosis of Cornea.—As a result of their studies Lewis and Montgomery believe that tuberculosis is primarily an exudative inflammation and secondarily proliferative in its character. More than that, they are led to the belief that the cellular exudate, protective though it may be in purpose, is defective and is destructive in its actual influence. Even the phagocytic activity of the cells of such an exudate may probably serve to distribute living bacilli and thus spread the disease to fresh areas.

40. Excretion of Nitrogen in Fever.—The rise of temperature following typhoid vaccination is accompanied by a marked increase in the output of total nitrogen, creatinin, and especially of uric acid. The reaction to tuberculin is slower, but is also accompanied by an increased output of nitrogenous substances, that is, however, less uniform and generally less pronounced. In a case of malaria studied by the authors there was a tendency for the rise of temperature to be accompanied by an increased output of total nitrogen and less uniformly of creatinin; on two days on which the fever was preceded by rigor the output of uric acid was increased.

41. Liver Function as Influenced by Ductless Glands.—Whipple and Christman found that adrenal insufficiency produced by extirpation of three-fourths or more of the gland tissue will be associated with a drop in liver phthalein excretion. With hypertrophy of the adrenal fragment the excretion comes back to normal, but may fall again when more adrenal tissue is removed. Pancreatic insufficiency causes a progressive fall in the phthalein excretion, indicating a grave lowering of the functional capacity of the liver. This fact has a direct bearing on the question of diabetes. Parathyroid insufficiency with tetany causes no decrease in phthalein output, but at times a rise above normal. This comes out best when the phthalein curve is low following pancreas extirpation. Parathyroid tetany may cause hyperactivity on the part of the liver cells. Thyroid insufficiency produces no change

in the uniform curve of phthalein excretion. Hypophysis insufficiency shows an initial fall in the curve, followed by a return to normal and a final drop in the last few days before death.

These experiments supply evidence to the effect that the liver is very much concerned in the derangement that follows the removal of the ductless glands. Hence it seems probable that this disturbance of the liver function may be an important factor in the general symptom-complex of ductless gland insufficiency.

55. Coccygodynia Treatment by Injections of Alcohol.—The treatment proposed by Yeomans is an application of the principle of injection of sensory nerves with 70 to 80 per cent. alcohol, thereby causing their degeneration as suggested by Schlösser in 1907. All of Yeomans' seven cases were of the type of neuralgia or neuritis of the coccygeal nerves in which this method is peculiarly applicable, though he thinks it should be tried in all cases of coccygodynia, whatever

their nature, as its application is simple and harmless. It may relieve the distressing pain even though it does not affect its cause. The patient, with rectum empty, assumes the left lateral (Sims') position on a firm table, with the thighs well flexed on the abdomen, and the region of the coccyx is painted with tincture of iodine. An all-glass Luer or similar sterile syringe of 2 centimeters capacity is filled with 90 per cent. alcohol and armed with a 2-inch needle of fine gauge. The right index finger is now inserted into the rectum and the point of maximum tenderness is determined by counter pressure with thumb outside. Maintaining the finger in the rectum to guard against its puncture and to act as a guide, the needle is now introduced through the midline directly to the painful spot. When this is reached the patient exclaims from pain that is exquisite but tolerable, and the injection of 10 to 20 minims is made slowly. The needle is withdrawn and its puncture sealed with collodion after neutralizing the iodine on the skin with alcohol. The pain from the injected alcohol lasts a few minutes only and may be followed by a dull ache for a day or two. As a rule, three and at the most five injections should suffice. The interval between the injections should vary from five to ten days—one week on the average—and they are to be made always at the joint which is found most tender at the time of injection.

70. Physiology of Gastric Motility.—By means of the local autonomous neuromuscular mechanism, Mallory states, the stomach is capable of performing its motor functions in an essentially normal manner, even when separated from the central and sympathetic nervous systems by section of both vagi and both splanchnic nerves. Normally, however, the gastric motor functions are modified by many extrinsic influences. Motor impulses, and those for increasing tonus and accelerating peristalsis, pass through the vagus nerves. These impulses are increased by mental excitement and impaired by physical exhaustion. Inhibitory influences, those for reducing tonus and retarding peristalsis, pass principally through the splanchnic nerves. These impulses are increased by mental depression and impaired by the internal secretions of the adrenals. The functions of the pyloric sphincter are under the control of conditions in the stomach, and are modified by nervous reflexes from the duodenum and small intestine.

The following agents have a sufficiently definite effect on gastric motility to be of therapeutic value; heat and cold applied to the abdomen externally; massage of the abdomen; atropin, physostigmin, pilocarpin, either by mouth or by hypodermic injection; hypophysis extract and suprarenal extract intravenously. Surgical operations performed on the stomach for the purpose of facilitating the discharge of gastric contents are sometimes only a partial success, or even an entire failure, when planned and executed in conformity with anatomic relations rather than physiologic considerations. The size, shape, position, tonus and capacity of the stomach vary under physiologic conditions. Therefore, in a gastro-intestinal anastomosis, the operation should be so performed and the stoma so situated that the discharge of gastric contents would not be hindered, but facilitated by the physiologic motility of the stomach. Gastric and intestinal peristaltic waves should run in the same direction. The stoma should be situated in the pyloric antrum, in which the expulsion of gastric contents will depend on peristalsis instead of gravity and in which it will be lowest when the stomach is nearly empty.

91. Tuberculosis of Bladder.—Keyes has modified Rovsing's treatment to the extent of employing phenol in instillation instead of irrigation, and in solutions of a strength varying in accordance with the sensitiveness of the patient. He begins with a solution of one to 200 of water and rapidly increases this to 1 per cent. before the patient complains of an increase in pain. The half dozen patients on whom he has been able to employ this technic have shown no great benefit until the solution reached a strength of from 2 to 5 per cent. In two instances he has even employed a super-saturated solution, drawing into the instillator a few minims of pure phenol, and then a few minims of water, thus making an emulsion, of which one or two minims may be instilled into the posterior urethra. The reaction from such an instillation is likely to be very marked. Its use is justified only where all else fails. It is not necessarily any more efficacious than the solutions.

93. Abdominal Incisions and Intra-Abdominal Pressure.—In four cases the esophagus was ligated by Horan through an incision in the neck, after placing a glass tube in the stomach, making the tube as secure and air-tight as possible with a ligature. An incision was made parallel to the umbilicus through the right rectus, and the rectum was ligated. The incision was closed in the ordinary manner, pressure being applied in all four cases to the full amount of the automobile gauge, viz., 120 pounds, and after the amount registered in one case, the pumping was continued until the abdomen looked to be twice the normal size. No hernia protruded in either case.

In two cases in which the incision was made in the right rectus, with the rectum ligated and the incision sutured, another incision was made in the median line from the sternum to the umbilicus, the tube was ligated within the stomach, and the incision was closed. In one case the pressure was 100 pounds and in the other 120 pounds. There was

no apparent rupture. There were six cases in which the incisions were made in the median line below the umbilicus, the pressure being introduced through the rectum in three, and through the stomach in the other three.

All cases herniated either through the sutures in the aponeurosis, or by a separation of the muscular fibers with pressure of 15 pounds in one case, 20 pounds in three cases, 40 pounds in one case and 110 in another. There were two cases in which transverse incision was made through the skin above the pubis, and the muscles were separated in the median line. One case with the tube in the esophagus, and the rectum ligated, withstood 120 pounds (male). The other case (female), the esophagus ligated with tube *in situ*, the rectum plugged with cotton, withstood but 40 pounds, a large hernia showing in the picture at 60 pounds.

In two cases in which the incision was made over the right rectus, the aponeurosis being dissected with the finger, the wound closed in the ordinary way; one cadaver withstood 80 pounds, the intestines puncturing at the cecum with about 10 pounds pressure in the other. The pressure was applied through the rectum in both cases, with the esophagus plugged with cotton. One case with an incision $5\frac{1}{2}$ inches long in the outer border of the rectus showed a hernia at the lower border of the incision, with 20 pounds pressure. In this case the ligature was placed at the duodenum, and pressure was applied through the rectum. In three cases with the incision over McBurney's point, with the muscles separated, the wounds closed; one case herniated with tearing of the muscular fibers at 20 pounds. There was no hernia in either of the other two cases. Two cases with the same incision, the muscles also incised, withstood 120 pounds, the pressure being applied through the esophagus. In three cases with the same incision as before, pressure applied through the rectum; one case herniated through the incision with 15 pounds pressure, the other two cases went over 120 pounds without pressure. In three cases of esophageal end of the stomach ligation through an abdominal incision, pressure applied through the rectum, two showed over 120 pounds pressure, and in the other the gut was punctured with about 10 pounds pressure.

In all of these cases the abdomen was left open. In seventeen cases the intestines were taken out of the abdominal cavity; only one of the number could be blown higher than 10 pounds. In all the other sixteen cases the air escaped almost as fast as it could be pumped in. This particular point shows the effect of low abdominal distention in some of the drainage cases.

95. New Instrument for Intravenous Injections.—The instrument devised by Frankel consists of: *A.* A perforated needle with a sharp cutting edge and point, about 2 to 3 inches long and about $\frac{1}{8}$ of an inch in diameter; the upper edge carries a crown-like arrangement within which fit a screw and cap to tighten the needle to the inner cannula. *B.* A cannula 1 inch longer than the needle, with a dull and rounded lower edge (so as easily to enter the lumen of the vein and be pushed within the vessel at least $\frac{1}{2}$ to 1 inch away from the point of injury, thereby preventing clotting, dislodgements, and spilling of the fluid within the tissues). This cannula fits snugly within the needle so as to be air-tight and still is very easily shifted in and out of the needle. The upper end of the cannula carries a crown like the needle, within which fits the third part. *C.* A perforated piece of metal whose upper part easily fits a piece of ordinary rubber tubing, while the lower end fits the upper part of the cannula. *D.* An ordinary piece of steel with sharp point called a stylet which keeps all parts together, clean and unobstructed, and can be used together with the cannula like a trocar for similar purposes.

1. Ailments in Camp: Their Significance and Prevention.—Webb-Johnson says, it is a well known fact that common ailments in camp are responsible for a great wastage of public money and a loss of training for a large percentage of men; the greatest number of admissions to hospital is among men with less than one year's service, and the lowest is among men with eight years or more experience; also that the rate of admission into hospital is highest among men between 20 and 25 and lowest among men between 40 and 50.

2. Gangrene in War.—Page says if the types of gangrene seen under war conditions be classified in accordance with their etiology, they group themselves under the five following headings: 1. Gangrene secondary to the interference with the blood flow through the main vessels of a limb. 2. Traumatic gangrene. 3. Infective gangrene. 4. Gangrene due to vasomotor paralysis. 5. Gangrene secondary to the effect of high explosives. The occurrence of the disease in young men with healthy circulatory systems is the one feature which is common to all these types, and which differentiates them on the average from gangrene as met with in civil practice. This fact considerably affects the line of treatment and the prognosis.

1. Gangrene of the extremities is occasionally seen as a result of direct slow velocity gunshot injury to the main brachial or femoral vessels; it more often occurs when a bone injury is present as well. High velocity rifle bullets may pass through large vessels and at the time produce few symptoms; subsequently an aneurysmal varix will very likely appear. The symptoms of this latter condition may be evident within a week or so of the injury, and if operation is undertaken at this stage, probably involving ligation of the artery above and below the sac, gangrene of the affected limb is likely

to occur. 2. Traumatic gangrene is a term theoretically applied only to those cases in which death of a part results from direct injury, but it is evident that infection will be an important factor in the extent and progress of the condition. 3. Acute infection with many organisms may cause some degree of local tissue necrosis. The term "infective gangrene," however, is usually reserved for those cases in which the process is definitely progressive and associated with toxemia. Under such a classification come phlegdema and the gangrene due to the bacillus of malignant edema and the *Bacillus aerogenes capsulatus*. 4. The cases of symmetrical gangrene which were seen by Page in large numbers among Turkish troops in the last months of 1912 resulted from a vasomotor disturbance. There were some differences of opinion in regard to the cause responsible for the condition. About half the men affected were suffering from enteritis. All gave a history of being exposed for long periods on wet ground and of having been on insufficient rations. Many had been in wet trenches for twenty-four hours on end; the temperature was usually 5 C. above freezing point. The gangrene was practically always symmetrical and affected the lower extremity in nearly all cases; the fingers were involved occasionally, but, as far as Page saw or could learn, never independently of the feet. The gangrene was usually dry, but in several of the more extensive instances it became moist, and there were several deaths from tetanus in this latter class of cases. When once the men were in the hospital the condition did not tend to advance except in the few instances in which emphysematous infection was superadded. Toxemia was not marked except under the latter circumstances. Page considers the condition to be strictly comparable to that of frostbite. The arterial circulation of the men affected was rendered extremely poor by the condition of starvation and fatigue; under these circumstances a temperature above freezing was able to produce stasis in the peripheral vessels. No doubt in some instances tight boots and puttees assisted, but many of the men affected had been wearing the loose native footwear. 5. Extensive gangrene of the extremities has been stated to occur in men after they have recovered from the effects of violent explosives. V. Berdisavljev, reporting from Servia, says he saw cases of hematuria, hemothorax, and shock as the result of explosions, but he says that in no instance did he see gangrene. Dr. Maclean had under his care in Constantinople a remarkable case of gangrene of all four extremities attributed to this cause. It will be appreciated that in general gangrene is merely an occasional complication of some other surgical condition, and that it only assumes epidemic importance under rare conditions of service.

4. Infection Following Elliot's Trephining Operation.—Griffith has trephined 125 times for primary glaucoma, by the method of Elliot, besides in a good many secondary glaucomas and for other diseases. He was well pleased with the results, and regards the operation as much more satisfactory than iridectomy in chronic glaucoma. A patient aged 55, had chronic glaucoma in both eyes. Both eyes were operated on within a short time of each other by upward trephining by Elliot's method, a small iridectomy including the pupillary margin being done, and the conjunctival flap was sutured. The patient was discharged in a month. Both eyes made perfect recovery and kept well for close on two years. He then presented himself with purulent iridocyclitis of the left eye. No light perception. Tension 3, exudation in the pupil, injection of the entire conjunctiva, edema of the lids, discoloration and inflammation of the iris; the pillars of the coloboma were free and well retracted. The eyeball was removed three days later. The eye had been affected four days. The other eye was still quite satisfactory in every way. The naked eye preparation of one-half the globe showed purulent cyclitis, the exudation covering the entire free surface of the ciliary body and posterior surface of the lens.

5. Causes of Blindness in Children.—The total number of blind and partially blind children from the blind schools of London brought by Harman into this inquiry is 1,100. The

causes responsible for their state of blindness may be placed in three groups: 1. Injury or destruction of the cornea consequent on surface inflammations. 2. Inflammation within the eyeball or optic nerve. 3. Congenital defects of the eyes. In the first group, injury or destruction of the cornea consequent on surface inflammations, ophthalmia neonatorum is responsible for by far the greater number of cases of blindness, and in particular for the cases of total blindness. The group contains 351 children, and the causes of the blindness are as follows: Ophthalmia neonatorum 266, 24 per cent., purulent conjunctivitis of later years 47, 4.2 per cent., phlyctenular keratitis 38, 3.4 per cent. The percentage for the grand total, 351, is 31.9 per cent.

The diagnosis of those cases marked "ophthalmia neonatorum," so far as the examination of the child at the time of school age is concerned, must rest on the character of the eye damage, the associated symptoms, and the history of the case as obtained from the parents or other responsible party. The cases of purulent conjunctivitis occurring in later months or years of child life were due to a great variety of causes. Eczema and streptococcal infections 4, scarlet fever 5, measles 10, German measles 1, meningitis 1, diphtheria 2, small-pox 4, erysipelas 1, chicken-pox 1, pneumonia 2, gonorrheal (contracted from vaginal discharge or pus from the eye of an affected baby) 2; total 47.

Group 2 contains a great variety of cases—inflammations of the cornea, of the iris, of the choroid and of the optic nerve; but it is sufficient for the purpose of these statistics to place them in two categories, according as the inflammation affected the anterior half of the eye or the posterior half. Those affecting the front half of the eye total 217, or 19.8 per cent.; by far the greater number are due to interstitial keratitis; there are a few only of iritis. Syphilis accounts for 17.8 per cent. Of those inflammations affecting the posterior half of the eye by far the greater number were due to a form of choroiditis known as "disseminated." This cannot be said to be diagnostic of syphilis, for other conditions are capable of causing the same or very similar conditions, but all evidence goes to prove that these cases are overwhelmingly syphilitic in origin. With the choroiditis there is always more or less atrophy of the retina and of the optic nerve, so that vision is gravely reduced. Closely associated with these cases are many cases of total optic atrophy. This group includes 222 cases, or 20.5 per cent. Of these, 126, or 56.7 per cent., were definitely syphilitic.

Group 3 includes 233 cases, or 21.2 per cent.; only 16, or 1.45 per cent., were known to be of syphilitic association. The figures show that there has been a definite diminution of the incidence of cases of blindness caused by ophthalmia neonatorum, and it is reasonable to credit this diminution to the great efforts that have been made to prevent the disease during the past few years. The apparent increase of the incidence of the cases of congenital syphilis is in part due to the diminution of the cases of ophthalmia, and in part to the use of finer methods of diagnosis. It is certain that the number of cases of blindness due to ophthalmia is diminishing both actually and relatively to the causes of blindness.

12 *Nitrogenous Metabolism in Chyluria. W. J. Young.

13 *Entamebiasis. Lim Boon Keng.

12. Nitrogenous Metabolism in Chyluria.—Young made a study of the albuminous matter and other nitrogenous constituents of the urine in two cases of chyluria. One case was that of a woman aged 42, otherwise healthy, who for twenty years had noticed that her urine became milky in appearance and clotted into jelly-like masses if left standing. She did not at first notice blood in the urine. Whereas formerly she had had no trouble on account of this, within the last ten years she had experienced dull, aching pains in the small of her back and had observed at times that the urine was stained with blood. On admission to the hospital specimens of blood taken both day and night were examined for filaria larvae, but it was never found to contain any.

The other patient was a miner aged 23. Eight years previous to admission he noted difficulty in passing urine and that it contained small, jelly-like, blood-stained clots, and also that the urine became milky on standing. He had dull, aching pains in his back. Otherwise the patient was quite well. Filaria larvae could not be found in the blood. Both were cases of true chyluria. The urines always contained fat which could be extracted with ether, but the milky appearance could not be entirely removed in this way. By the technic described by Young 1.8 per cent. of fat was found in the urine of Case 1 and 2.6 per cent. in that of Case 2. A quantity of protein was present which showed the properties of the proteins of the lymph. It coagulated when the urines were heated to 70 to 75 C., and contained globulin precipitated by half saturation with ammonium sulphate, and an albumin when the liquid was completely saturated with this salt. In Case 1 a fairly complete analysis of the nitrogenous constituents of the urine was made daily for fourteen days by a technic described in the article.

The patient whose weight, unfortunately, was not taken, was maintained on a diet consisting of lean meat, bread and potatoes, the nitrogen content of which was approximately 15 gm. The quantity of protein nitrogen excreted daily varied from 0.49 to 1.94 gm., the average for the fourteen days being 0.95 gm. per diem, corresponding approximately to 6 gm. protein. The complete results are given in a table, which shows a low grade of nitrogenous metabolism. The non-protein nitrogen representing protein actually utilized in metabolism was very small in quantity, the daily average excretion being 6.39 gm. This represents approximately 40 gm. protein catabolized. Aside from the protein nitrogen the other constituents of the urine showed a normally balanced nitrogenous metabolism.

In Case 2 the patient was kept on two different diets. During the first eight days the diet consisted of lean meat, eggs and bread carefully weighed out and equal in quantity to 15.4 gm. nitrogen per diem, while in the succeeding six days a diet of eggs, milk, bread and butter was employed. The daily quantity of urine varied from 1,120 c.c. to 3,195 c.c. The daily loss of lymph proteins as determined by the albumin in the urine averaged 2.40 gm. nitrogen, equivalent to 15 gm. protein. It varied from 10 gm. to 21.5 gm. The details are given in a table. During the first eight days the protein catabolized daily, as represented by the non-protein nitrogen, averaged 11.89 gm., approximately 74 gm. protein, which is about normal. The patient consumed the whole of the food given and did not find the amount excessive. During the second period, however, when the diet was controlled by the appetite of the patient, the quantity of nitrogen excreted decreased steadily, the non-protein nitrogen falling as low as 6.1 gm. daily, corresponding to only 38 gm. protein catabolized, a figure below normal. It was still decreasing when the experiment ceased.

13. Entamebiasis.—The relation of rheumatic pains, erythema and prurigo with dysentery and hepatic abscess, has been noted since the days of Graves and Murchison. Keng's observation is that all rheumatic inflammations and rheumatism as seen in Singapore, are associated with a protozoan organism, found in the intestinal canal in many persons, but mainly in those suffering from rheumatism, bronchitis, asthma, an irregular remittent fever, various inflammations, sciatica, lumbago, urticaria, erythema marginatum, erythema nodosum, prurigo, impetigo herpetiformis, lichen rubra acuminata, and chronic gastrodynia. One patient had painful micturition as if passing gravel, the urine being red and having a brick-dust deposit. In many of these patients, the organism is also found in the sputum, the urine, in the blood and in the skin eruptions.

It is Keng's impression that at least two distinct species (that producing dysentery, liver abscess and their inflammations; and that giving rise to rheumatism and its allies) may be clinically admitted although it is possible that in dysentery we have to deal only with a special phase of the multiplicative stage. This question of the relationship between dysentery and the rheumatic states cannot be settled. It is almost

impossible at times to say from microscopic examinations that the ameboid bodies found in endometritis, bronchopneumonia, and skin sinuses are not the *Entamoeba histolytica*. The different diseases named are often found in persons who have had an attack of dysentery, although the greater number of those rheumatic and gouty patients have never had dysentery.

The association of the parasite in its different stages with different diseases is as follows: I. Fungus-like plasmodium, constipation. (a) Few free amebas in the feces, flatulence, biliousness, hepatic congestion, headache, vertigo, dizziness, pyrosis, nervous symptoms, urticaria. (b) Granular ameba also present in sputum, pharyngeal irritation, colds and bronchitis. (c) Free ameba plentiful in feces, sputum and blood, rheumatism, with arthritis and heart disease, toxemia, typhomalarial type of fever, acute urticaria, prurigo, boils, etc., tonsillitis, sciatica and gravel. II. Multiplicative phase. Large granular ameba undergoing fission, schizogony and budding by means of chromidia shedding, acute dysentery, acute gastritis and colitis, bronchopneumonia, bronchiectasis and phthisis, adenitis metritis and pelvic abscess, peritonitis, nephritis, appendicitis, hepatic abscess, pyemia. III. Encysted stage. Recovery for the time being or improvement in the patient's condition. Relapse occurs when the cysts burst and the parasites resume the active rôle. IV. Parasites in all stages flourish in the blood in extensive areas and affect the kidneys, with cachexia, anasarca, anemia, debility, sweats.

As far as Keng can make out the parasite is a mycetozoon and is a form of chlamydomysca. The fungus stage closely resembles a mycetozoa which he has found in house drains and is almost indistinguishable from a parasite in the intestinal canal of fowls. Provisionally, we may call it *Chlamydomysca toxifera* on account of its toxic effect on man.

17. Habitual Swallowing of Aerated Saliva.—Hayem regards this as a form of aerophagia and as by far the most common type. This sialophagia should be suspected, he says, in every case of gastro-intestinal tympany. Auscultation over the stomach will generally reveal the gas entering and leaving the stomach, and sometimes the gas can be heard in the stomach. The sound more frequently heard from it is a borborygmus as the aerated saliva enters the stomach from the esophagus. He regards this sialophagia as a reflex act from some abdominal organ and suggests that it may reveal something wrong in this organ, especially if it happens to be the stomach, before any other signs point to it.

18. Reinfection with Tuberculosis.—The extensive experimental work here reported was for the purpose of studying the reaction of the skin of tuberculous guinea-pigs to reinfection with large doses. Special attention was paid to the histologic aspect of the reinoculation lesions and the behavior of the tubercle bacilli in them. When the reinoculated guinea-pig was under the influence of preexisting tuberculosis, the reinfection manifested itself always as an acute hemorrhagic inflammation with necrosis. The lesion appears

in twenty-four hours instead of the incubation of from eight to twelve days with a primary inoculation. The lesion also heals completely sooner or later, thus differing from the incurable skin lesion of a primary infection. In the reinoculation lesion the tubercle bacilli all die off in time. These differences from the behavior of a primary skin lesion confirm the assumption of a state of allergy.

32. Surgical Treatment of Cavity in the Lung.—Frangenheim regards operative treatment as indispensable for a cavity in the apex if it persists little if any modified after all the other tuberculous processes in the lungs have healed. Baer has reported success from surgical treatment of cavities in both lungs. The chances are better when the sheets of the pleura are adherent, but a cavity in the apex with open pleural cavity does not absolutely contra-indicate intervention. With a very large and thin-walled cavity, there is danger of the wall's suffering from inadequate blood-supply. Roentgenoscopy and the exploring finger warn of this. In treatment of a cavity in the upper lobe, he insists that pneumolysis offers better chances than operations on the chest wall. By "pneumolysis" he means operative mobilization of the upper lobe after the cavity has been emptied by gravity, the patient reclining on his side for an hour. A stretch of a few centimeters is resected from the second or third rib in front and, through a lengthwise incision in the periosteum behind, the finger is worked through between the fascia and the costal pleura and the upper lobe is loosened up all around to correspond to the extent of the cavity. An opiate before the operation prevents reflex phenomena and the whole operation can be done under local anesthesia, dabbing the pleura with the anesthetic solution. He has never had any hemorrhage worth mentioning.

When the part of the lung with the cavity is thus mobilized, the cavity may be obliterated by compression from a paraffin or other filling injected between the pleura and the chest wall. Various drawbacks have been encountered with different fillings; paraffin is so heavy it is liable to slide down below the cavity. It has also been known to work its way outward

through the breach in the ribs and entail a suppurating fistula. Friction from the paraffin has also caused gangrene of lung tissue in some instances. Compression of the lung by an inflatable bag introduced into the extrapleural space is liable to lead to infection. Wilms uses fat tissue as the filling, and this seems the best of all for the purpose, provided it is not too rapidly absorbed. Mayer insists that the pneumolysis alone, without any filling, is all that is necessary at first. Later, if the lung shows a tendency to expand and open up the cavity again, nitrogen could be injected to fill the space. Both Wilms and Baer insist that the filling procedure need not be restricted to old, chronic, shriveling cases, but can be applied in a recent process with cavities: there need be no fear that the procedure in itself will aggravate the tuberculosis. The cavity is influenced by the pneumolysis much more than by a thoracoplastic operation, while the heart, the lungs elsewhere and the muscles controlling expectoration are not impaired by it. When the technic for filling the extrapleural space is further perfected, the pneumolysis method will certainly be found extremely valuable for treatment of cavities in the lungs, especially in the upper lobe, while with diffuse pulmonary disease extensive thoracoplastics answers the purpose better.

35. Prognosis of Cardiovascular Disease.—Among the points emphasized by Bockhorn is that the heart and the vascular system are one, as is evident from the embryonal development. Thus what acts on the peripheral circulation acts on the heart as well. He refers in particular to the effect of sea bathing and sea air, saying that he knows of far more people living to 90 and over in good health in seashore towns than in the inland, other conditions approximately equal. Neurasthenics should be sent systematically to the seashore for a course of training; if this were done regularly, cardiovascular disease might be warded off in a large proportion of cases. In arteriosclerosis, the process might be arrested and other vascular regions saved from involvement if there were seashore sanatoriums and convalescent homes available. Bockhorn states that tests have shown that the North-Sea bathing represents a course of cold, carbonated, brine baths and such are regarded by many as the most effectual form of balneotherapy in treatment and in prophylaxis of cardiovascular disease.

38. Mechanism of Asthma.—Winter ascribes the attack in asthma to some irritation of the vagus; this causes, by reflex action, some disturbance in the blood-vessels in the lungs. The blood-vessels become enlarged and more easily permeable, and this readily explains the symptoms observed.

40. The Chemistry of the Coagulation of the Blood.—Stuber and Heim have continued their research on the influence of lipoids on various biologic processes, on phagocytosis and coagulation, and here report that there is a direct connection between the fat-splitting and the coagulation-inducing

properties of ferments. Steapsin proved the most active in both lines. Chemically pure stearic acid, and tristearin in a lesser degree, are able to induce coagulation of the blood as promptly as or even more effectually than thrombokinase. In respect to their influence on the coagulation of the blood, the fat acids can be classified in a homologous series, their place in which is determined by the number of carbon atoms in the molecule. The arrest of coagulation by leech extract comes under the workings of this law. The first phase of the coagulation process is thus a lime-fat soap production; the second phase is the lime-fat soap fibrinogen, the lipolytic ferment serving as catalyzer. The latter—blood-lipase—seems to be under the control of certain glands with an internal secretion.

41. Serodiagnosis of Pregnancy.—Freund and Brahm report the application of Abderhalden's technic in 114 pregnant women and in 36 controls, men and non-pregnant women. The test gave negative findings in 18.4 per cent. of the pregnant women and a positive reaction was obtained in 53.1 per cent. of the men and the non-pregnant women. Thus the test failed in nearly 27 per cent. of 135 cases. They report further some additional series showing equally disappointing results with various modifications of the technic. They applied the antitrypsin method along with the Abderhalden in 48 pregnant and 16 non-pregnant women, or in men, and incorrect responses were obtained once with the antitrypsin method and seven times with the Abderhalden among the pregnant, and seven times with the former and ten times with the latter among the controls, including some normal or syphilitic men. Neither test proved absolutely reliable, but the antitrypsin test was much more so than the Abderhalden while its technic is simplicity itself in comparison, especially E. Rosenthal's modification of the original Fuld-Gross method. Heimann and Chotzen obtained correct responses with it in all of 66 controls and in 47 of 50 pregnant women, and R. Franz's tests of 223 pregnant women have confirmed the value of the test; a negative reaction may be accepted as positively excluding pregnancy. Franz remarks, however, that as the test is merely a sign of increased metabolism of albumin and is not specific for pregnancy, a positive response must not be regarded as a sign of pregnancy unless it is possible to exclude other conditions accompanied by augmented destruction of albumin, such as cancer, tuberculosis, nephritis, exophthalmic goiter and fever from any cause. . . . Lindig uses desiccated and pulverized placentas for the test, or casein in substance.

42. Colorimetric Determination of the Sugar in the Blood.—With the technic described the sugar content in normal adult males ranged from 0.05 to 0.07 per cent. A diabetic with 6.2 per cent. sugar in the urine had 0.2 per cent. sugar in the blood. In four healthy infants the sugar content ranged from 0.029 to 0.036 per cent. In order to obtain comparable findings, Autenrieth and Montigny emphasize the importance of agreeing on a standard test meal and standard interval before applying the test, as food containing much sugar, such as honey, increases materially the percentage of the sugar in the blood.

43. The Tuning Fork-Stethoscope Method.—Olpp commends Cantlie's method of using the tuning fork in connection with the stethoscope to determine the outline of the viscera, of tumors, etc. The method can be applied to one's own body. Gynecologists may find that this method will reveal a tumor in the uterus or elsewhere that escapes all other methods of investigation.

44. Operative Treatment of Stab and Gunshot Wounds of the Heart.—Müller relates an instance of an apparently insignificant wound of the heart which entailed fatal internal hemorrhage while another, much more serious apparently and sutured at once, terminated in recovery. The bullet was not found in the latter case and still can be seen with the Roentgen rays about two finger-breadths above the diaphragm. The heart was sutured with catgut in this case and the young man has been apparently in perfect health during the months since. In this as in most of the cases on record

the bullet hole through the soft parts suppurated but the inflammation did not extend below. Recovery is known in 53 per cent. of 51 operative cases on record; in the latest 10 cases, 9 of the patients were cured. Müller's other patient was a girl of 10 who fell on a glass roof and cut herself slightly at several points. The quarter-inch cut in the third left interspace was not considered serious at first but an operation two hours later revealed a glass splinter which had cut the left ventricle. The 1-cm. wound was sutured with silk and the heart-beat grew stronger at once but the child had lost so much blood that she was unable to rally and died in two and a half hours after the operation. The sharp splinter of glass had struck the third rib and been deflected into the left ventricle.

46. **Infectious Erythema.**—Heisler reports an epidemic of this affection last spring embracing twenty-five cases. It sometimes came on with a stormy onset, fever and glandular enlargement accompanying the maculapapulous erythema on the cheeks, possibly becoming confluent and giving the face a peculiar bloated appearance. The color of the erythema was a bluish red; in a day or so it extended down on the upper arms and toward the back of the neck and shoulder-blades. The second or third day the buttocks and outside of the thighs developed the erythema likewise, but nowhere was it confluent except on the face. The eruption is briefly transient and sometimes comes and goes and returns, all with equal suddenness. No connection with any other infectious disease was apparent in his experience. The epidemic broke out first in a boys' boarding school in the middle of a term. The incubation period was from five to fourteen days, generally seven, and direct transmission from child to child could be traced in each new case. The swollen region in the face generally showed some desquamation later and there was a tendency to pigmentation in a few cases. The spleen was not enlarged in any instance and the urine was normal except for the presence of indican in a few cases. The fleeting nature of the erythema aided in differentiation but the most characteristic finding was the sudden enlargement of the glands below the ear and toward the occiput. This preceded by a day or so the erythema.

47. **Serodiagnosis of Cancer.**—Weinberg gives the details of 12 cases in which malignant disease seemed certain but the Abderhalden test gave negative findings, and the further course of the cases disproved cancer. In 28 cases of cancer the test was positive in all but 2 and in one of these the cancer had developed so suddenly and actively that possibly there had not been time for the specific ferments to develop. In 15 controls the reaction was constantly negative. Contrary to the experiences related by others, Weinberg found that carcinoma serum digested carcinoma-tissue alone, and sarcoma serum, sarcoma-tissue alone; the special organ involved seemed immaterial. The specific tissue is the main point; spindle-celled sarcoma would not respond to round-celled and vice versa, and the same occurred with cylinder-celled carcinoma, etc. Lack of realization of this peculiar specificity may explain the conflicting experiences published by some workers in this line. In 8 cases the reaction persisted positive after the removal of the cancer and in each instance this was explained by the discovery of metastases.

56. Durable Collargol Preparations of Spirochetes, etc. (Herstellung der haltbaren Kollargolpräparate von Spirochäten und Hyphomyzeten.) J. Saphier.

49. **Vaccination Treatment of Tuberculosis.**—Weichert explains on the basis of the side-chain theory Piondoff's success in treating tuberculosis by systematically repeated vaccination—like an intensified Pirquet tuberculin test, repeated about once a month. He assumes that the skin and mucous membrane are the seat of especially vigorous antibody production as they bear throughout life the brunt of bacterial attacks. Other arguments to sustain this assumption are presented, including the success of vaccination against small-pox. The article is continued.

50. **Improved Technic for Electrocardiography.**—With the ordinary technic one never knows from what part of the heart the electric current is proceeding, and hence it is impossible to obtain records under exactly similar conditions for comparison with other cases or even with other records of the same organ. Mayer says that he has overcome this difficulty by taking the record as the patient reclines in a zinc tub filled to a certain mark with water. The volume of the body plus the water is thus always the same, and the area of conduction is so large and so far from the heart that minor differences become equalized.

51. **Injections of Blood in Leukemia.**—Kiralyfi calls attention to the stimulating effect on the bone-marrow of intramuscular injections of defibrinated blood when the patient has been taking benzol or Roentgen treatment to excess; that is, when the benefit apparently being realized from the treatment suddenly gives place to an acute exacerbation, which is a frequent occurrence. In a case reported in detail, a merchant of 59 with myeloid leukemia for about six months improved after six days of benzol treatment, the whites dropping from 31,000 to 13,000, and the benzol was discontinued. The whites continued to drop until they numbered only 2,150 and the reds dropped to 1,000,000 and the patient suffered intense pains in his limbs. A venesection had just been done to relieve a patient with polycythemia, and 10 c.c. of the blood drawn from this patient was injected into the gluteal muscle of the leukemia patient. By the next day the whites had climbed to 7,000 and by the fourth day to 11,900 and the reds numbered 150,000 more, showing that the exhausted bone-marrow had begun to recuperate. The injection was repeated with ordinary blood nine days and again three weeks later, and the improvement continued. The complexion became natural, the swollen glands subsided, and the previously bed-ridden patient was able to be up and about. The reds have kept since at about 2,000,000 and the whites from 9,000 to 10,000.

54. **Treatment of Syphilis of the Nervous System.**—Gurari has been applying Swift and Ellis' technic and later a modification of it and reports considerable improvement in a number of the cases. Ten are described in detail with the findings on repeated lumbar puncture. He makes an intravenous injection of neosalvarsan and an hour later draws the blood, but instead of aspirating it he introduces the needle alone into the vein after a constricting band above has been drawn tight. Then the band is removed and the patient works his fingers, the forearm pendent. Blood then pours out of the needle almost as if it came from an artery; the blood is received in a glass vessel with a broad bottom. It is set aside for twenty-four hours, when the serum is ready for use, clear and without a trace of hemolysis. He has applied this procedure forty-five times, estimating the results by the chemical, histologic and serologic findings in the cerebrospinal fluid as the criteria. In six of the ten cases reported in detail the pleocytosis was materially reduced; in three nearly to normal with one injection, in the others not until the second or third injection. The Nonne reaction subsided also parallel to the pleocytosis. The Lange and Wassermann were the hardest to influence, especially the Lange. It persisted in some cases after five injections, long after the Wassermann had disappeared. The clinical course

showed improvement in the subjective symptoms, the pains and other sensory disturbances, but the symptoms from the far-advanced anatomic changes naturally were not influenced.

59. **Technic for Pyelography.**—Lichtenberg says that he has applied pyelography about a thousand times and this experience has confirmed the necessity for preliminary thorough purging, also the advantage of using a catheter impregnated with bismuth in certain segments alternating regularly with non-opaque segments. This permits distances to be readily estimated. The larger the supposed dilatation of the kidney pelvis, the longer must be the delay before injecting any fluid. With hydronephrosis, even in its incipient stage, there may be obstruction to the reflux of the fluid injected and a typical attack of colic may ensue. After a few hours or days the fluid injected may be emitted with urine at intervals, this keeping up for eight or ten days. He has observed intervals up to two and a half days. This intermittent stoppage, as shown by pyelography under the Roentgen rays, is an absolutely reliable sign of latent incipient hydronephrosis, according to his experience. The fluid injected is also liable to be retained in cavities and ulcers; he regards this as an advantage rather than otherwise, as the silver salt he injects for the pyelography exerts a direct healing influence. If the mucosa is sound it is smooth and the injected fluid rapidly reaccumulates in the bladder. He warns that pyelography is contra-indicated if there is hemorrhage.

- 70 *Vaccine Therapy of Typhoid. II. V. Pensuti.

70. **Vaccine Therapy of Typhoid.**—Pensuti states that relapses occurred in 25 per cent. of thirty-seven cases of typhoid in which antityphoid vaccine had been applied in treatment. He theorizes to explain this enhanced tendency to relapse, and reports a series of thirty-one new cases in which the vaccine was given by another technic, based on the theory he advances. He injected the usual therapeutic dose

and then continued with minute doses, keeping this up even for a few days after the temperature had returned to normal. The injections even of the minute doses were followed each by a brief rise, demonstrating the instability of the defensive forces, but they evidently reenforced them as recovery proceeded smoothly and there were no relapses in the entire series.

August 8, No. 30, pp. 287-296

- 75 *Case of Gynecomastia. C. Werneck.

73. **Neuritis of Malarial Origin.**—Britto's patient was a young man with paralysis of the nerves innervating the muscles of the right eye. There was a history of mild venereal disease but the blood contained the malaria germ and under quinin the ophthalmoplegia promptly subsided. Without microscopic examination of the blood the true cause of the trouble would scarcely have been suspected.

74. **Atypical Rabies.**—In the case reported a man of 60 developed symptoms which suggested rabies at first but they soon subsided and he seemed calm and cheerful and took baths and his meals normally, and the diagnosis was changed to incipient general paralysis. The fifth day the patient was found depressed and apathetic, with paralysis of the legs, and he died in a few hours. The necropsy findings proved the case to have been true rabies beyond question, but the man had never been bitten by any animal. He had told, however, that a few months before he had hurt his leg slightly and an old dog of his had licked the small sore and the dog had disappeared not long afterward.

75. **Case of Gynecomastia.**—Werneck says that in the case illustrated, the abnormal development of the mammary glands in a mentally backward young man was evidently secondary to atrophy of the testicles and cryptorchidism. The low blood-pressure and readiness to fatigue indicate insufficiency of the adrenals.

May 30, LVIII, No. 22, pp. 1845-2044

- 76 *Arguments Why the Practice of Medicine Should be Restricted to Those Trained in Medical Science. (Arztenmonopolie en Geneesvrijheid.) C. A. Pekelharing, H. Treub and Others.

76. **Arguments for Safeguarding the Practice of Medicine.**—A movement is on foot in the Netherlands the aim of which is to throw down all the barriers that now protect the sick against ignorance and unscrupulous exploitation. The 200 pages of this issue of the *Tijdschrift* are devoted entirely to a survey of the value and necessity of the present safeguards, twenty-six leading physicians considering the subject from different standpoints, the whole forming an able protest against any letting down of the bars. B. J. Polenaar, a lawyer, tells of the numerous and far-reaching changes that would have to be made in the present laws to protect the public health and the sick in case the practice of medicine were to be thrown open to all. J. Slingenberg reviews the legislation in various countries in turn which regulate the practice of medicine; Germany and England, he says, are the only civilized countries which do not require a medical degree, and in Prussia alone the number of the untrained dealing in the healing art has risen from 2,404 in 1898 to 6,137 in 1905. C. A. Pekelharing traces the history of medicine from ancient days to the present, showing how superstition and mysticism have always hampered the progress of medical science and how strict science alone can be the basis for suitable treatment. C. Winkler shows that the

history of medicine seems to be a chain of errors and yet how at every point there is evidence that relative truth has emerged from the errors. Empiricism leads the way and scientific medicine follows. H. Treub, in an extremely interesting analysis of the differences between the charlatan and the trained physician, compares the untrained practitioner of medicine to a blind man stumbling around in a dark room seeking something he does not know what; while the scientific physician is like a normal man in a well lighted room seeking an object with which he is familiar.

The standing of physicians and the practice of medicine in ancient Greece and Rome and in the middle ages are discussed by K. Kuiper, J. W. Beck and M. A. van Andel. The charlatan as portrayed on the stage in the Netherlands and in Dutch literature is described by J. te Winkel while G. van Rijnberk tells of the quack in Dutch art, reproducing several engravings; he discusses further modern "miracle cures," hypnotism and magnetism. P. Muntendam depicts the harm done by books for home doctoring, written in a popular style, of which Germany has so many. He remarks that even those written by physicians have their disadvantages, but it is difficult to overestimate the harm done by the books of a Bilz, a Kuhne or other quacks.

The methods of various quacks and cults are described in a number of articles, H. U. Meyboom writing of Christian Science and the Emmanuel Movement, J. Stärcke of Amsterdam telling of the absurd and dangerous practices of many exponents of the drugless school. Household and folklore remedies are discussed by E. C. van Leersum and P. van der Wielen. Homeopathy and its erroneous conception of the action of drugs are discussed by H. Pinkhof of Amsterdam, and the dangers which would confront the public if the practice of medicine was not safeguarded are described by several writers. The way in which infectious diseases would spread and cancer progress unchecked if the movement for throwing open the practice of medicine to the untrained should succeed, are well shown by H. G. Ringeling and S. Mendes da Costa of Amsterdam. The latter emphasizes this in particular for venereal diseases and J. Rotgans for cancer. The harm that would be done to the public health, to social medicine and to social hygiene by removing restrictions to the practice of medicine is shown well by J. G. Sleeswijk, professor of hygiene at the University of Delft. The waste of money from quack practices is reviewed by E. J. Abrahams, who remarks that it is impossible to estimate the sums squandered for worthless or sometimes dangerous quack remedies, but he knows that quacks pay annually at least 800,000 florins for their advertisements in the papers and periodicals of the Netherlands. W. Nolen of Leyden reviews some of the latest achievements of medicine and comments on some of the disappointments it has encountered in recent years, and suggests new lines for further conquests. H. Schreve, medical director of the Rotterdam public hospital, concludes the series with instances of serious injury from the procedures of the naturopaths.

The issue closes with a book-review department, reviewing a number of new German and Holland works bearing on quackery and its menace to public health. The pamphlets issued by the leaders of a similar agitation in Germany are also analyzed and answered point by point.

78. The Changes in the Nervous System with Beriberi.—Honda gives some colored plates of the pathologic-histologic findings in a number of cases of beriberi emphasizing the

characteristic and constant changes as they occur in both the central and the peripheral nervous systems. The pathologic findings are less pronounced in the peripheral nerves with acute than with chronic beriberi, but the extent of the nerves involved as a whole is greater than with the chronic form. He defines the acute form as that in which the nerves of more vital importance, the phrenic and vagus nerves and the nerves of the extremities are affected early and with great intensity. In the chronic cases the less vitally important nerves are affected early and intensely but those of great vital importance escape entirely or nearly entirely. In two infants with beriberi the changes in the nerves corresponded more to those of the acute form in adults although the clinical picture was more like that of the adult chronic type. Honda applies the Bielschowsky technic to specimens embedded in celloidin, and thinks that this modification of the otherwise ideal Bielschowsky technic is a great improvement. The specimen is not loose and can thus be easily handled; different stains can be applied to the same specimen, and mechanical injury in cutting frozen sections is done away with. He discusses the history of work on the nerves in beriberi and reviews the literature, tabulating the details of the histologic findings in his twenty-six cases.

82. Uterine Cancer.—This and some other articles in this issue were read at the first general meeting of the All-Russian Association for the Campaign against Cancer. Kakushkin thinks that both the abdominal and the vaginal routes have their indications. The latter is best for incipient cases and when the body of the uterus is involved. The abdominal method should be preferred when there is parametritis with adhesions, and then the transverse incision is desirable. He advises hysterectomy even for benign hyperplasia of the cervix and erosions in prophylaxis of cancer.

83. Dangers of Injuring the Vagus in Operations on Tumors in the Neck.—Weber reports five cases to show the serious dangers liable from reflex action when the vagus is injured in operations on the neck, and cites Reich's compilation of forty-four cases with five deaths. For these reasons he urges the importance of blocking the nerve with a 20 per cent. cocaine solution, above and below the tumor, to ward off trouble if it should happen to be injured. One of Weber's five patients succumbed half an hour after the operation. The others recovered but one was left with paresis for a time.

84. Potassium Iodid in Diagnosis and Treatment of Cancer.—Mikhailoff strongly recommends potassium iodid in internal cancer, preferably in the form of rectal injections (4 gm. potassium iodid; 2 gm. sodium carbonate and 80 or 100 c.c. distilled water). This he supplements with 1 per cent. solution of sodium arsenate (sodium arsenici) hypodermically, which solution must be made with 0.25 per cent. phenol. He found that if the temperature rises one or two hours after the rectal injection of the potassium iodid, then we positively have to do with a malignant growth (carcinoma or sarcoma). If the temperature remains stationary or even declines, then cancer can be excluded and syphilis is probable. He sees in

the action of potassium iodid in this respect an analogy to the action of tuberculin in tuberculosis, and claims that carcinoma can be cured in certain stages of malignant disease with this method of treatment. It reveals the presence of cancer like the positive response to the tuberculin test in tuberculosis, and a systematic course of treatment with it has a curative influence like that of tuberculin.

He states that potassium iodid seems to display a special affinity for cancer cells in the test-tube, and his clinical experience apparently indicates that this is the case also in the human body. For the differential diagnosis, he gives the rectal injection as above described, and repeats it after an hour or hour and a half to a maximum of three injections, but one is generally sufficient. The temperature reaction becomes manifest in one or two hours. He does not give specific instances or figures, but relates that after his course of treatment with potassium iodid supplemented by subcutaneous injection of a 1 per cent. solution of sodium arsenate, some of the patients are still living who had been told years before by leading clinicians that they had internal and hence inaccessible cancer. All his patients thus treated were in this inoperable class, as he always operates for accessible cancer.

85. Fish Poisoning.—Konstansoff found the bacillus of fish poisoning in two kinds of fish. Very small doses of pure agar cultures killed white mice in from six to twelve hours. As this bacillus is very similar to the *Bacillus botulinus* of van Ermengem, Konstansoff thinks that it is probably a variety of the latter.

86. Laryngectomy for Cancer.—Mintz has removed the entire larynx on account of malignant disease in 29 cases, and tabulates here the details of each. Seven of his patients (24 per cent.) lived for more than a year, and 3 are in good health to date over seven, eight and twelve years since the operation. It is remarkable that the two patients who have survived the longest both required a second operation for recurrence in a gland four and twenty months after the primary laryngectomy. The ultimate outcome in a number of the other cases is not known later than a few months.

90. Muscle Sign of Chronic Appendicitis.—Volkovitch found that in chronic appendicitis, or in intervals between acute attacks, the abdomen is relaxed in the right iliac region contrary to what is usually observed in acute appendicitis. In addition the abdominal muscles on the right side seem to shrink and atrophy. The more pronounced this so-called muscle sign, the severer is the appendicular lesion. This sign is absent with inguinal hernia, but Volkovitch is unable so far to tell if it is positive in other lesions of the right abdominal cavity, such as pelvic lesions in females, gall-stones, etc. The relaxed condition of the abdominal muscles in chronic appendicitis may lead to scoliosis on the left side, and he asserts that left-sided scoliosis should raise suspicions of a possible chronic appendicitis.

acute inflammation follows if the trauma is very much pancreatic juice was forced out, while the mere production of a cyst if the injury was slight. In another of his cases the cyst was secondary to the cancer found with it, the cancer having the tissues like a trauma. The four other patients had recurring attacks of pain, and gall-stones were necropsy in two cases. These were probably the causes of attacks of pain, and the passage of a stone may have stretched the opening leading up into the pancreas resulting destruction of pancreas tissue and cyst.

In the other cases the attacks of pain and of transient jaundice retrospectively suggest gall-stones. Search was made for them at the operation on the 11th. The pains, however, were always localized on the right side. The smaller the cyst the more difficult the diagnosis. The case the symptoms seemed to suggest perforation of ulcer or peritonitis but the signs of pleuritis and albuminuria did not agree with this, and Roemer's examination revealed an accumulation of fluid just below the left diaphragm. Treatment can be only surgical, so the lips of the cyst to the skin with care not to let the contents of the cyst come in contact with the skin. There is a defined lining of the cyst in the class of cases here in which digestion of tissue is responsible for the destruction. Any attempt to cut out the cyst merely entails more destruction and may entail hemorrhage except if the cyst is found circumscribed and lined with epithelium. It is merely a small corrosion cyst in the head of the pancreas.

96. Corrosion of Esophagus from Lye.—The child drank a swallow of lye and the stomach was rinsed out once. A few days later the lining of the esophagus was thrown up in the form of a nearly perfect tube 14 cm. long. The esophagus was systematically dilated with a catheter passed down into the stomach once a day for about three months and then at longer intervals, and the child has had no further signs of trouble. The catheter was introduced for the first time twelve days after the lye was swallowed, seven days after the lining of the esophagus had been cast off. The text-books warn not to begin catheterization until after there is no more blood or pus in the mucus, that is, not for three to six weeks, but Zachariae's plan of warding off stenosis in this case suggests that it is better to commence earlier. Rovsing found it impossible in this case to introduce even the finest sound one month after the caustic had been swallowed. It is also a question whether the dilatation must be kept up. Bloch advises it occasionally all through life, to ward off recurrence, and Zachariae another patient who had return of trouble after 60 years after the lye injury occurred during childhood. It is certainly a wise plan, he remarks, to let no month pass without introducing the catheter once, as prevention in these cases is easy while it is so hard to cure inveterate stenosis.

97. Rupture of the Mesentery.—Sand says that there have been only five cases of this during the last ten years at the Copenhagen public hospital; Prutz has recently collected forty-four cases. The mortality in the operative cases is 38 per cent. while all died in the cases in which no operation was attempted. The exact diagnosis is never possible until the abdomen is opened and then it is always a question whether the bowel should be resected or not. In doubt, it is safer to do the resection. He describes in a typical serious case successfully treated on these principles.
